Republic of China

Purpose: To determine the association between preoperative lumbar epidural injections (LEIs) in the operating theater (OR) and the occurrence of surgical site infection (SSI) after posterior lumbar instrumented fusion surgery.

Methods: This study was performed from January 2015 to September 2019. We enrolled 2312 patients who underwent lumbar surgery without LEIs (control group) and 469 patients who underwent lumbar surgery after LEIs in the OR. We further separated the patients by the time interval between the LEIs and surgery: 1) for the 0–1 M group, lumbar surgery was performed within 1 month after the LEIs, and 2) for the >1 M group, it was performed more than 1 month after the LEIs.

Results: The postoperative infection rate in the 0–1 M group was considerably higher than that in the control group ($p = 0.0101$). We further subdivided the 0–1 M and >1 M groups into four subgroups: a) the 0–1 MNS group included patients in the 0–1 M group who did not receive steroids; b) the 0–1 MS group who received steroids; c) the >1 MNS group included patients in the >1 M group who did not receive steroids; d) the >1 MS group who received steroids. The postoperative infection rate in the 0–1 MS subgroup was considerably higher than that in the control group ($p = 0.0018$). However, the infection rate was lower in the >1 MS subgroup ($p = 0.1650$). There were no statistically significant differences in the postoperative infection rate between the control group and the two non-steroid groups (0–1 MNS group, $p = 0.4961$; 1 MNS group, $p = 0.7381$).

Conclusion: The administration of LEIs without steroids in the OR before lumbar instrumented fusion does not significantly increase patients' risk of postoperative infection. We recommend avoiding steroid injections administered within 1 month before lumbar instrumented fusion.

Keywords: epidural injections, postoperative complications, spine puncture, surgical wound infection

Introduction

Low back pain, which leads to limitations in activity and the loss of productivity, is one of the major health care issues worldwide. Almost everyone suffers from low back pain at some point in their lives.¹ Low back pain and its related radiculopathies are one of the most common reasons individuals in the US seek medical care.² Lumbar disc herniation, degenerative disc disease, and facet joint dysfunction are common causes of low back pain.³ Lumbar epidural injections (LEIs) are commonly used to treat chronic low back pain. Some studies have shown that local

Correspondence: Xiuwei Hou
Email Houxiuwei111@163.com

anesthetics or steroid injections can effectively alleviate low back pain by suppressing inflammatory mediators and increasing blood flow to ischemic nerve roots.^{1,4-6} However, another study reported that epidural steroid injections can only provide short-term rather than long-term pain relief.⁷ LEI procedures can be used for diagnostic or therapeutic purposes prior to lumbar surgical interventions.

Although a LEI is generally considered a safe procedure, it is associated with several complications, such as hematomas, allergic reactions, and infections.^{8,9} Infections after lumbar surgery have a considerable impact on recovery. The infection rate after posterior lumbar instrumented surgical procedures is approximately 3%.¹⁰ A recent nationwide database study reported that patients who undergo lumbar fusion < 3 months after LEIs may suffer from a higher postoperative infection rate.¹¹ In addition, the US Food and Drug Administration has not approved the injection of corticosteroids into the epidural space due to infections.⁵ However, Seavey et al¹² reported that preoperative LEIs do not increase the postoperative infection rate. These conflicting data suggest that the true effect of preoperative LEIs on postoperative infection remains unclear. The purpose of this study was to assess the association between preoperative LEIs in the operating theatre (OR) and the incidence of SSI after posterior lumbar instrumented fusion surgery.

Methods

Patient Selection

A comparative prospective study including a series of patients who underwent instrumented posterior lumbar fusion for degenerative disc disease in our medical center after January 2015 was performed after the institutional review board at our hospital approved the study. The inclusion criteria were a diagnosis of lumbar disc herniation or another degenerative lumbar spine disease confirmed by radiological examination; predominantly chronic low back pain associated with radicular symptoms lasting more than 6 months; and participation in medical therapy or physical rehabilitation for more than 3 months without improvement. Patients who had a history of a minimally invasive procedure not performed in the OR, lumbar surgery, or a spinal infection and those who did not attend a follow-up after the procedure were excluded. This study was approved by the ethical committee of The Second Affiliated Hospital of Luohe Medical College

(2014-11-01), written informed consent was obtained from the participants, and the study was performed according to institutional guidelines and the Declaration of Helsinki.

Through September 2019, a total of 3212 patients underwent lumbar instrumented fusion in our medical center. A total of 2781 patients who met the inclusion criteria were enrolled in our study. There were 1665 female and 1116 male patients, with an average age of 60.5±6.6 years (range from 47 to 78 years). A total of 2312 patients who underwent lumbar instrumented fusion without LEIs were included in the control group, while the other 469 patients had undergone LEIs in the OR before lumbar instrumented fusion. According to a previous report, patients who underwent lumbar surgery within 1 month after LEIs had the highest infection rate.¹¹ Therefore, we subdivided the patients in our study by the time interval between the LEIs and surgery: 1) the 0–1 M group included patients for whom lumbar surgery performed within 1 month after LEIs, and 2) the >1 M group include those for whom surgery was performed more than 1 month after the LEIs.

All the LEI procedures were performed under C-arm in a sterile OR. The patients were placed in a comfortable prone position, and the skin was sterilized. After local anesthesia, the segmental level was identified, and the tip of the needle was placed in the lower third foramen under fluoroscopy. Lidocaine with or without steroids was administered. A few weeks after the LEIs (usually 1 to 12 weeks), posterior lumbar instrumented fusion was performed. All the lumbar surgeries were performed by two senior specialists (X.H. and L.P.). The patients were followed up for more than 6 months after posterior lumbar fusion to determine whether they developed a surgical site infection related to the operation.¹³

Statistical Analysis

Statistical analyses were performed using Prism software for macOS (version 8.2.1). Comparisons between groups were performed by Student's *t*-test, the chi-squared test, or Fisher's exact test. We also calculated the odds ratio and 95% confidence intervals. $p < 0.05$ was considered to indicate statistical significance.

Results

There were 469 (16.9%) patients (282 females and 187 males) in the injection group and 2312 (83.1%) patients (1383 females and 929 males) in the control group. The average age of the patients was 60.5±5.8 years for the

Table 1 Preoperative and Intraoperative Characteristics and Clinical Outcomes

Characteristics	Injection Group (N = 469)		Control Group (N = 2312)	p value	
	0-1M Group (N = 258)	>1M Group (N = 211)		0-1M Group	>1M Group
Age* (yr)	60.4 ± 5.9	60.6±5.8	59.4 ± 6.8	0.373	0.2638

Abbreviation: BMI, body mass index.

injection group (range, 48 to 78) and 59.4±6.8 years for the control group (range, 47 to 78). The 469 patients were divided by the time interval between the LEIs and lumbar surgery. The 0-1 M group included patients with a time interval of less than 1 month (258, 55.01%), and the >1 M group included patients with a time interval of more than 1 month (211, 44.99%). The patient characteristics are shown in Table 1. All these patients underwent posterior lumbar decompression with pedicle screw fixation and bone graft fusion. No significant differences were found between the 0-1 M/>1 M group and the control group in blood loss or the number of fused levels ($p > 0.05$). The postoperative infection rate for the 0-1 M and >1 M groups are presented in Table 2. The infection rate of the 0-1 M group was 6.98% (18/258), which was higher than that of the control group (3.51%, 81/2312) (odds ratio (OR) 1.99, range 1.21-3.22, $p = 0.0101$). In the >1 M group, the infection rate decreased to 5.21% (11/211), and there was no significant difference between the control group and the >1 M group.

We subdivided the 0-1 M group and >1 M group into non-steroid (NS) and steroid (S) subgroups according to whether the patients received a steroid injection. We did not find a significant difference between the 0-1 MNS

(patients in the 0-1 M group who did not receive a steroid injection), >1 MNS (patients in the >1 M group who did not receive a steroid injection), and >1 MS (patients in the 0-1 months group who received a steroid injection) subgroups and the control group ($p = 0.4961, 0.7381, \text{ and } 0.1650$, respectively). However, the infection rate was much higher in the 0-1 MS subgroup (patients in the 0-1 M group who received a steroid injection) ($p = 0.0018$) than in the control group (Figure 1).

Discussion

There are some studies on the association between LEIs and the infection rate after spine surgery. However, these existing studies reported conflicting results.^{10,11,14,15} Recently, Signla et al¹¹ found that the risk of postoperative infection significantly increased when the LEIs were performed within 1 month prior to nonfusion lumbar decompression ($p < 0.0001$). The results of our study showed that the administration of LEIs within 1 month before lumbar spinal instrumentation fusion significantly increased the incidence of SSI, which is consistent with the results of the study by Signla et al.¹¹ However, we found that the administration of LEIs without steroids before lumbar spinal instrumentation fusion did not increase the odds of SSI in either the 0-1 MNS group or the >1 MNS group ($p = 0.4961$ and 0.7381 , respectively).

The exact mechanistic link between LEIs and postoperative infection remains unknown. Potential etiologies may be direct contamination, skin flora inoculation or immunosuppression of steroids. For patients undergoing total knee arthroplasty (TKA), intra-articular injections should be avoided within 3 months prior to surgery.¹⁶ Most intra-articular injections are performed in a therapeutic department, not in the OR. However, all the LEIs in our prospective study were performed in the OR,

Table 2 Postoperative Infection Rate in the Injection Group versus the Control Group

Variable	Injection Group		Control Group
	0-1M Group	>1M Group	
No. of individuals	258	211	2312
No. of postoperative infection (%)	18 (6.98)	11 (5.21)	81 (3.51)
Odds ratio (95% CI)	1.99 (1.21-3.22)	1.51 (0.816-2.80)	NA
p value	0.0101 [†]	0.2458	NA

Note: [†]Significant.

which has a much cleaner environment than a does a therapeutic department. Thus, the administration of LEIs in the OR could significantly reduce the introduction of exogenous bacteria into the spinal space. When the effects of the steroid were excluded, the risk of an infection was not increased in either non-steroid group (0–1 MNS and >1 MNS). Thus, if LEIs without steroids are administered for diagnostic purposes in the OR, there is no need to wait 3 months before performing lumbar surgery, such as TKA or THA.^{16,17}

However, corticosteroids are a type of anti-inflammatory drug used to treat autoimmune diseases, and the topical administration of corticosteroids might decrease patients' immune response following surgery. Thus, having received a steroid injection is a risk factor for local infection, such as abscess, discitis, and meningomyelitis.^{18–20} Although there is a low infection rate following epidural steroid injection, the infection can be magnified by lumbar instrumentation fusion. It has been reported that steroids can dysregulate the host inflammatory response to pathogen exposure and tissue injury, which results in an increased susceptibility to postoperative infection.^{14,21} In our study, the injection of steroids within 1 month before lumbar spinal instrumentation fusion significantly increased the incidence of SSI (10.48%, $p = 0.0018$). This increased level of risk decreases as the time interval between LEIs and spinal surgery increases. The administration of LEIs with steroids more than 1 month prior to lumbar spinal instrumentation fusion did not lead to a significant increase in SSI ($p=0.1650$). A meta-analysis of 14 randomized controlled

trials showed that the effectiveness of steroids was significantly superior to that of saline only and local anesthetics at 1 month, and the efficacy of steroids along with the associated adverse effects diminished after 1 month.²² This finding explains why the postoperative infection rate significantly diminished after 1 month prior to lumbar fusion. To explore the mechanism of infection associated with topical steroid application, the pharmacokinetics of LEIs with steroids should be studied further.

Another reason for the inconsistency between our results and those of other reports^{11,14} is that we included longer follow-up periods. Most postoperative infections occur between three days and three months after lumbar surgery, but they can take as long as six months to develop, especially after instrumented spinal fusion.²³ All the patients in our study were followed up for more than 6 months postoperatively, and no patients were lost to follow-up.

This study had some limitations. First, all the injection-timing groups were relatively small, including fewer than 20 patients, and were likely underpowered to detect small but statistically significant differences between groups. Second, our study population was only limited to patients enrolled in a single institution; thus, it may not reflect the general population. Third, the observer biases cannot be avoided, because both the patients and doctors know the treatment methods.

In conclusion, it is relatively safe to perform LEIs in an OR. However, steroids may significantly increase the incidence of infection. There is a potential increased risk of postoperative infection in patients who undergo preoperative LEIs with steroids within 1 month prior to lumbar

instrumented fusion. We recommend waiting more than 1 month after the steroid injection to perform lumbar surgery.
