ABSTRACT: Recent studies have identified butanone as a promising biomarker in the breath of lung cancer patients, yet the understanding of its gas-sensing properties remains limited. A key challenge has been to enhance the gas-sensing performance of materials toward butanone, particularly under ultraviolet light exposure. Herein, we report the synthesis of a novel three-dimensional composite material composed of $SnO₂$ incorporated with $Bi₂O₃$ using facile hydrothermal and impregnation precipitation methods. Detailed physical and chemical characterizations were performed to assess the properties of the developed material. Upon activation with ultraviolet light, our composite exhibited exceptionally high sensitivity to butanone. Remarkably, the butanone response was nearly 3 times greater for the Bi_2O_3 -loaded SnO_2 composite than for pristine SnO_2 , achieving a response value of 70. This substantial improvement is due to the synergistic effect of the material's distinctive three-dimensional architecture and the presence of $Bi₂O₃$, which significantly augmented the gas-sensing capability of butanone. To elucidate the underlying gas-sensing mechanism, we conducted first-principles calculations using density functional theory (DFT). The computational analysis revealed that the $Bi₂O₃$ containing system possesses superior adsorption energy for butanone. Ultimately, our findings suggest that the Bi-SnO₂ composite holds great promise as an optimal sensing material for the detection of butanone under ultraviolet illumination.

■ **INTRODUCTION**

Human beings are increasingly exposed to toxic, harmful, flammable, and explosive gases from industrial production activities. These polluted gases have incredibly harmful impacts on the ecological environment and human health. To protect people from gas leakage and pollution, monitoring of flammable, explosive, toxic, and harmful gases are of great necessity.^{1−[4](#page-10-0)} The volatile organic compound (VOC) butanone is widely used in interior decoration, industrial production, and pharmaceutical manufacturing. It has been reported in the literature that butanone stimulates human eyes and neuron systems and is used as a biomarker in the exhaled breath of lung cancer patients.[5](#page-10-0)−[9](#page-11-0) Therefore, a material exhibiting efficient sensing of butanone gas is increasingly needed.

As vital gas-sensing materials, metal oxide semiconductors (MOSs) have been widely investigated due to their high sensitivities and low detection limits.^{[2](#page-10-0),[10,11](#page-11-0)} A number of gassensitive materials based on metal oxides have been synthesized and used to detect butanone. Vioto et al.^{[7](#page-10-0)} prepared a SiO₂@CoO core−shell structure with a high specific surface area, and gas-sensing test results showed that it detected 2-butanone effectively. The excellent gas-sensing performance may be attributed to the high surface area provided by the unique core−shell structure. Weng et al.^{[8](#page-10-0)} fabricated coral-like Zn-doped $SnO₂$ hierarchical structures assembled from nanorods. Its efficient detection of butanone may be attributed to the Zn doping and unique structure. As a

Figure 1. Schematic illustration of the synthesis of the Bi_x -Sn_{1−*x*}O₂ hierarchical structure.

typical MOS, $SnO₂$ is a wide band gap n-type semiconductor with high electron mobility. Sensors based on $SnO₂$ generally show excellent responses to various gases and have the advantages of low costs and long service lives. However, pure SnO₂-based sensors usually exhibit weak responses and poor selectivities and require high operating temperatures.^{[12](#page-11-0)−[15](#page-11-0)}

According to literature reports, the gas-sensing properties of MOS materials are related to their unique physical and chemical properties and the microstructures of the surfaces.¹⁶ Generally, materials with large specific surface areas and porous structures exhibit better gas-sensing performance.^{[15,17](#page-11-0)} The hierarchical structure constitutes a three-dimensional nanomaterial structure with a geometric shape formed by selfassembling of low-dimensional nanomaterials. Compared with other nanostructures, the three-dimensional hierarchical structure with the high specific surface area enables significantly enhanced gas detection by the material, which has excellent potential application value and research value.^{18,[19](#page-11-0)} Zhu et al.^{[20](#page-11-0)} prepared Y-doped SnO₂ hierarchical flower-like nanostructures via a one-step hydrothermal method. Characterization results indicated that the excellent sensitivity to formaldehyde was due to the Y-doping and the unique three-dimensional hierarchical structure. The sensitivities and selectivities of composite metal oxide-sensitive materials can be improved by changing the compositions. Therefore, this approach has received extensive attention from researchers.^{[21,22](#page-11-0)} Another effective method to enhance gas sensitivity is by combining other metal oxides with tin dioxide to form a composite structure. Such a structure not only increases the surface area for gas adsorption but also allows for the adjustment of the adsorption capacity, significantly enhancing the sensitivity of the sensor. Bang et al. grew Bi₂O₃ branches on SnO₂ nanotubes using the vapor-liquid– solid method, thereby developing a gas-sensitive material with excellent detection capabilities for $NO₂$ gas. The outstanding detection performance of this gas-sensitive material primarily stems from the high specific surface area generated by the $Bi₂O₃$ branches and the formed $Bi₂O₃$ – $SnO₂$ heterostructure. As a typical n-type semiconductor, $Bi₂O₃$ is widely used in

optoelectronic devices and gas sensors due to its excellent physical and chemical properties.^{[23,24](#page-11-0)} David et al.^{[23](#page-11-0)} successfully prepared a highly sensitive $Ag/Bi₂O₃$ composite nanomaterial using the precipitation method and applied it to monitor toluene in the air. The addition of Ag enhanced the gas-sensing properties of $Bi₂O₃$ through various mechanisms, thus achieving high-sensitivity detection of toluene gas at room temperature, making it a superior gas sensor material. In addition to compounding with other materials, the ability of the material to detect VOCs can also be improved by irradiation with ultraviolet (UV) light.^{25−[27](#page-11-0)} Hyodo et al.²⁸ reported that the gas-sensing performance of the material was improved by UV irradiation. Saidi et al. 29 29 29 reported that the capabilities of WO_3 -based gas sensors for VOCs were significantly improved by UV irradiation. However, to the best of our knowledge, the use of Bi_2O_3 -loaded SnO_2 nanostructures for detecting butanone with UV irradiation has yet to be studied. In conclusion, considering the important practical application value of developing a sensor that can effectively detect butanone, we note that current research on using the impregnation precipitation method to load Bi_2O_3 onto the surface of $SnO₂$ nanostructures is not sufficient. The impact of these materials on the gas sensitivity of butanone, especially under ultraviolet light irradiation, has not been explored in depth. Therefore, the aim of this study is to fill this gap in the research field and provide new insights for the efficient detection of butanone.

In this study, we synthesized $SnO₂$ with a three-dimensional hierarchical structure with a facile hydrothermal method and subsequently prepared a series of samples with different $Bi₂O₃$ loadings. Their use in detecting butanone under UV irradiation was investigated. The results indicated that combining the $Bi₂O₃$ and UV light significantly improved the gas-sensing performance. In addition, we explored the mechanism for butanone detection by the Bi containing $SnO₂$ with firstprinciples theoretical studies.

■ **EXPERIMENTAL SECTION**

Materials and Reagents. All chemicals in the experiments were of analytical grade and used without further purification. Stannous sulfate (SnSO₄), trisodium citrate (C₆H₅Na₃O₇· $2H_2O$), sodium lauryl sulfate $(C_{12}H_{25}SO_4Na)$, bismuth nitrate $(Bi(NO_3)_3·5H_2O)$, ammonia solution $(NH_3·H_2O)$, and ethanol $(C₂H₅OH)$ were purchased from Sinopharm Chemical Reagent Co., Ltd. Deionized water was used throughout all of the experiments.

Synthesis of the Bi*x***-Sn1**−*x***O2 Hierarchical Structure.** In a typical synthesis process, initially, 5 mmol of tin(II) sulfate (SnSO4) and 5 mmol of sodium citrate tribasic dihydrate $(C_6H_5Na_3O_7.2H_2O)$ were dissolved in 40 mL of a mixed solution consisting of deionized water and anhydrous ethanol at a volume ratio of 1:1. Subsequently, 0.5 mmol of sodium dodecyl sulfate $(C_{12}H_{25}SO_4Na)$ was dissolved in 20 mL of deionized water. Afterward, these two solutions were stirred separately for 30 min at room temperature using a magnetic stirrer. Then, the two solutions were combined and stirred for another 30 min. Once stirring was complete, the solution was transferred to a stainless-steel autoclave lined with polytetrafluoroethylene and heated at 180 °C for 24 h. After the reaction was finished, the autoclave was allowed to cool naturally to room temperature. The collected precipitate was then centrifuged and washed several times with anhydrous ethanol and deionized water (8000 rpm for 10 min). Afterward, the product obtained from centrifugation was dried in an oven at 80 °C for 12 h. Finally, the dried powder was transferred to a muffle furnace and annealed at 500 °C for 2 h.

Using the impregnation method, we prepared a series of Bi_xSn_{1−*x*}O₂ hierarchical structure materials with molar ratios *x* $=[Bi]/([Bi] + [Sn])$ of 0.0, 1.0, 2.0, and 3.0. First, 200 mg of the sample was weighed and dispersed in 60 mL of deionized water with stirring. In the process of preparing the bismuth nitrate solution, an appropriate amount of bismuth nitrate $(Bi(NO₃)₃·5H₂O)$ was dissolved in dilute nitric acid. Then, the dispersed $SnO₂$ sample was mixed with a bismuth nitrate solution. During stirring, ammonia−water was added dropwise to adjust the pH to 11, followed by continued stirring at room temperature until precipitation occurs completely. The obtained precipitate was centrifuged and washed using a mixture of anhydrous ethanol and deionized water, a process that was repeated three times (8000 rpm for 10 min). Subsequently, the centrifuged product was dried in an oven at 80 °C for 12 h. Finally, the dried powder was transferred to a muffle furnace and annealed at 500 °C for 2 h.

A schematic diagram showing the Bi_x -Sn_{1-*x*}O₂ synthetic process and loading strategy is shown in [Figure](#page-1-0) 1.

Material Characterizations. The composition and structure of the material were characterized with X-ray powder diffraction (XRD) (Bruker D8 Advance, with Cu K*α* radiation $(\lambda = 0.15406$ nm), 40 kV, and 40 mA). The microscopic morphologies and sizes of the particles were recorded with a field emission scanning electron microscope (FESEM, Gemini SEM 300, 10.0 kV) equipped with an EDS detector. Energy dispersive X-ray spectroscopy (EDS, XFlash610-H) was used to study the distributions of the elements. To obtain more detailed information on the morphologies and structures of the samples, they were observed with a transmission electron microscope and a high-resolution transmission electron microscope (HRTEM, JEM- 2100, 200.0 kV). The specific surface areas and pore size distributions of the samples were measured with the Brunauer−Emmett−Teller (BET, ASAP 2460, Micromeritics Instruments) method. XPS measurements were performed by X-ray photoelectron spectroscopy (XPS, Thermo Scientific, ESCALAB 250XI, *hν* = 1486.6 eV). Charge correction was carried out with the standard C 1s peak at 284.80 eV. UV−vis measurements were carried out with a PerkinElmer Lambda 750 spectrophotometer.

Fabrication and Measurement of Gas Sensors. The gas-sensing capabilities of the samples were measured with a WS-30B gas-sensing analysis system (Weisheng Instruments Co., Zhengzhou, China), and the gas sensor fabrication and gas-sensing test methods were previously reported.^{[30](#page-11-0)} In a typical sensor fabrication procedure, the synthesized samples with varying loading ratios were pulverized into fine powders with an agate mortar. One of the resulting powders was mixed with an appropriate amount of ethanol to form a viscous slurry, which was ground for 1 h. A ceramic tube was coated with the ground slurry using a fine brush, ensuring uniform coverage. The coated tube was subsequently dried in an oven at 80 °C for 2 h. A heating coil comprising a Ni−Cr alloy was inserted into the ceramic tube and then welded to the sensing element base. Subsequently, the ceramic tube was also welded to the sensing element base. To improve the stability of the device, the gas sensor was aged at 200 \degree C for 120 h. The relative humidity in the test chamber was approximately 20% during the test.

To ensure the accuracy and reliability of the gas sensors, we performed a series of calibration procedures before the measurements. First, based on the technical parameters and experimental scheme of the test system, we appropriately set the number of test channels, acquisition speed, test voltage, and other parameters. Then, we turned on the equipment, allowing the sensing elements to reach the working temperature and maintain it for a predetermined time. Subsequently, without adding any test gases, we conducted a baseline test on the test system. Afterward, we injected the target gas at a known concentration (such as butanone) into the gas chamber and recorded the response value of the corresponding gassensitive element. At different concentrations, we plotted the response curve according to the sensor's response and verified the sensitivity and precision of the sensor by comparing the actual response of the sensor with the theoretical value. After the above steps, we are confident that the gas sensors have been fully calibrated before measurement, thus ensuring the accuracy and reliability of the measurement results.

In this study, we utilized a static gas distribution method to evaluate the gas sensitivities of the sensors. During the gassensing tests, the UV light was provided by UV lamp tubes emitting a wavelength of 365 nm. The response of the gas sensor was calculated as $S = R_a/R_g$, where R_a is the resistance of the sensor in air and R_g is the resistance of the sensor in the target gas. The response times (T_{res}) and recovery times (T_{rec}) of the gas sensors were defined as the time required for the resistance to reach 90% of its steady-state value after insertion into or removed from the target gas to be measured.

■ **RESULTS AND DISCUSSION**

Structure and Composition Analysis. XRD analyses were conducted on samples with varying loading ratios, and the results are depicted in [Figure](#page-3-0) 2. All of the samples exhibited strong diffraction peaks, demonstrating their high crystallinities. Additionally, no diffraction peaks from impur-

Figure 2. XRD patterns for Bi_x - $Sn_{1-x}O_2$ ($x = 0.0, 1.0, 2.0,$ and 3.0%).

ities were detected. All of the diffraction peaks were indexed to the tetragonal rutile phase of $SnO₂$ (JCPDS No. 41-1445, space group $P4_2/mnm$, $a = 4.738 \text{ Å}$, $c = 3.187 \text{ Å}$.^{[11](#page-11-0),[15](#page-11-0)} No diffraction peaks for Bi or its oxides were found in the XRD spectrum. This was attributed to the low proportion of Bi on the $SnO₂$ surface, which surpass the XRD detection thresh- $old.^{15,31}$ $old.^{15,31}$ $old.^{15,31}$ The positions and half-height widths of the peaks were unchanged, suggesting that the crystalline $SnO₂$ was not affected by $Bi₂O₃$ loading.

The morphologies of the pure $SnO₂$ and $Bi_{0.02}-Sn_{0.98}O₂$ samples were characterized with field emission scanning electron microscopy (FESEM) (Figure 3). Figure 3a shows an FESEM image of the pure $SnO₂$ hierarchical structure. The image clearly displays the flower-like hierarchical structure, which was formed by self-assembly of nanosheets. Figure 3b shows higher magnification FESEM images, and the results indicated good homogeneity and a monodisperse morphology. The nanosheets present relatively smooth surfaces with edge thicknesses of approximately 20−30 nm. Figure 3c,d shows FESEM images of the $Bi_{0.02}$ -Sn_{0.98}O₂ hierarchical structure at different magnifications. There were no significant changes in the structures and particle sizes of the samples after Bi loading, suggesting that the prepared $SnO₂$ samples were very stable. Figure 3d shows that a small number of nanoparticles were dispersed on the surfaces of the material. These particles could be precipitated by $Bi₂O₃$.

Figure 3. FESEM analyses with different loading ratios; (a, b) pure SnO₂, (c, d) Bi_{0.02}-Sn_{0.98}O₂, and (e−g) EDS element maps of Bi_{0.02}-Sn_{0.98}O₂.

Figure 5. Typical N₂ absorption−desorption isotherms and Barrett-Joyner-Halenda (BJH) pore size distribution curves (inset) for pure SnO₂ (a) and $\text{Bi}_{0.02}$ -Sn_{0.98}O₂ (b).

Figure 6. UV−vis absorption spectra and calculated band gaps (inset) for pure $SnO₂$ and $Bi_{0.02}$ - $Sn_{0.98}O₂$.

To demonstrate the presence of $Bi₂O₃$ nanoparticles on the surface of the $SnO₂$, EDS elemental mapping was carried out with the 2.0 mol % $Bi-SnO₂$ nanostructure, as shown in [Figure](#page-3-0) [3](#page-3-0)e−g, and this indicated the spatial distributions of Sn, O, and Bi, respectively. It is clear that Bi was uniformly distributed on the surface of the material.

The microstructure of the $\text{Bi}_{0.02}\text{-}\text{Sn}_{0.98}\text{O}_2$ was also characterized by TEM and HRTEM, and the results are shown in Figure 4. Figure 4a is a low-resolution TEM image, and it showed that the sample had a flower-like hierarchical structure assembled from nanosheets. The thicknesses of the nanosheets were approximately 20−30 nm, which was consistent with the results of the FESEM analysis. The HRTEM image (Figure 4b) revealed clear lattice fringes, indicating that the prepared samples were highly crystalline, which was consistent with the XRD analyses. The measured interplanar distances were approximately 0.336 and 0.264 nm, which corresponded to the (110) and (101) crystal planes of the tetragonal rutile phase of $SnO₂$, respectively.^{32,3}

The BET-specific surface areas of the prepared samples were also determined. Figure 5a,b illustrates the nitrogen adsorption and desorption isotherms for pure $SnO₂$ and $Bi_{0.02}-Sn_{0.98}O₂$, respectively. The specific surface areas of the samples were determined with the Brunauer−Emmett−Teller (BET) equation, and the specific surface areas of the pure $SnO₂$ and $Bi_{0.02}$ - $\text{Sn}_{0.98}\text{O}_2$ were 6.298 and 7.296 m²/g, respectively. According to the IUPAC classification, the samples exhibited typical type IV adsorption isotherms with H3 hysteresis loops, indicating typical mesoporous structures. $34,35$ The inset figure in Figure 5

Figure 7. XPS data for pure SnO_2 and $Bi_{0.02}$ - $Sn_{0.98}O_2$; (a) full spectrum and (b) Bi 4f, (c) Sn 3d, and (d) O 1s spectra.

Figure 8. Responses of the samples with different loading ratios to 100 ppm butanone with or without UV irradiation.

illustrates the pore size distribution. The pore sizes of pure $SnO₂$ and $Bi_{0.02}-Sn_{0.98}O₂$ were concentrated within the range of 2−10 nm. The pore size distribution curves indicated relatively narrow pore size distributions, with median pore sizes of approximately 2.18 and 2.38 nm, respectively. The relatively

narrow pore size distributions and large pore volumes of the material indicated high porosity, which is commonly associated with effective adsorption and gas detection, which was consistent with the results of the gas-sensing studies. $36,37$ Enhancing gas-sensing performance is a complex process that not only depends on the specific surface area of the material but also involves the collective effect of various factors. For instance, the activity of adsorption sites is an important factor that cannot be overlooked. The number and type of these active sites directly affect the performance of the material's gassensing properties. We discovered that even among materials with similar specific surface areas, the gas-sensing performance may differ due to variations in the adsorption site activity. Therefore, we need to further analyze the mechanism behind the enhancement of gas-sensing performance through other characterization methods.

The UV–vis spectra of the pure SnO₂ and $\text{Bi}_{0.02}$ -Sn_{0.98}O₂ are shown in [Figure](#page-4-0) 6. All samples exhibited strong ultraviolet absorption peaks. The band gap is a crucial parameter for semiconductor materials, and $SnO₂$ is a typical direct semiconductor material. In this study, the Tauc method was used to calculate the band gap energy $(E_{\rm g})$: $(\alpha h \nu)^2 = B(h \nu E_{\sigma}$), where α is the absorption coefficient, *h* is the Plank constant, *ν* is the photon frequency, and *B* is a constant relative to the material.^{[38](#page-11-0)} The inset shows plots of $(ah\nu)^2$ versus $h\nu$ for pure $SnO₂$ and $Bi_{0.02}-Sn_{0.98}O₂$. The linear portions of the

Figure 9. (a, b) Response−recovery curves for pure SnO₂ and Bi_{0.02}-Sn_{0.98}O₂ with 1–200 ppm butanone.

Figure 10. (a, b) Response–recovery curves for detection of 100 ppm butanone by the pure SnO₂ and Bi_{0.02}-Sn_{0.98}O₂ sensors at the optimal working temperature.

curves were extended to the horizontal axis ($y = 0$), and the intercept is the band gap. The calculated band gaps were 3.51 and 3.30 eV for pure $SnO₂$ and $Bi_{0.02}-Sn_{0.98}O₂$, respectively. The introduction of $Bi₂O₃$ resulted in a decrease in the band gap, which was attributed to an increase in the number of surface defects and a synergistic effect from the heterojunctions between the $SnO₂$ and $Bi₂O₃$ particles.³⁶ A lower band gap energy facilitates electron transfer from the valence band to the conduction band, resulting in enhanced gas sensitivity.^{[5](#page-10-0)} In the gas sensitivity tests, we employed UV light with a wavelength of 365 nm to irradiate the samples. The photon energy was calculated with the formula $E_{\rm g} = 1240/\lambda$ and yielded a value of 3.40 eV, which exceeded the band gap of the material after loading. This facilitated the absorption of photons that promoted electrons from the valence band to the conduction band, and more electron−hole pairs were produced. This enhancement of the carrier density contributed to the heightened gas sensitivity of the material.³⁵

To analyze the elemental composition and chemical states of the material surface, X-ray photoelectron spectroscopy (XPS)

was applied to pure $SnO₂$ and $Bi_{0.02}$ - $Sn_{0.98}O₂$. All spectra were calibrated with the C 1s peak at 284.8 eV, as shown in [Figure](#page-5-0) [7](#page-5-0). [Figure](#page-5-0) 7a contains the full XPS spectrum from $Bi_{0.02}$ - $Sn_{0.98}O₂$, in which the peaks for Sn, O, and Bi can be observed. This indicated the presence of Sn, O, and Bi in the material. [Figure](#page-5-0) 7b−d contains the high-resolution Bi 4f, Sn 3d, and O 1s spectra, respectively. The high-resolution Bi 4f spectrum is contained in [Figure](#page-5-0) 7b. The peak at approximately 164 eV was attributed to the Bi $4f_{5/2}$ state, while the peak at approximately 159 eV corresponded to the Bi $4f_{7/2}$ state. This indicated the presence of Bi^{3+} on the surface of the material.^{40,[41](#page-11-0)} The highresolution Sn 3d spectrum is shown in [Figure](#page-5-0) 7c. The binding energies of the two peaks were approximately 486.8 and 495.2 eV for the Sn $3d_{5/2}$ and Sn $3d_{3/2}$ states, respectively, and the distance between the two peaks was 8.4 eV. This indicated the presence of Sn^{4+} in the sample, which was consistent with results reported in the literature.^{[22,](#page-11-0)[42](#page-12-0)} The high-resolution O 1s spectrum is illustrated in [Figure](#page-5-0) 7d. As shown, three types of oxygen species were present on the surface of the material. The peak at approximately 529.5 eV was associated with the lattice

oxygen (O_L) present on the surface of the material, while that at approximately 531.2 eV was linked to oxygen defects (O_V) on the surface. Additionally, the peak at approximately 532.5 eV corresponded to chemically adsorbed oxygen (O_C) on the surface of the material. $43,44$ In comparison with those of pure SnO₂, the O_V and O_C concentrations in the $Bi_{0.02}$ -Sn_{0.98}O₂

Figure 13. Schematic illustration of the mechanism for the synergistic effect of UV light irradiation and $Bi₂O₃$ loading in enhancing the ability of $SnO₂$ to detect butanone.

sample were significantly higher. The abundant O_V sites provided more sites for adsorption and reactions of gases on the surface of the sensing material. The increased O_C proportion suggested that more oxygen species were adsorbed on the material surface. $1,18$ $1,18$ $1,18$ It was inferred that samples loaded with $Bi₂O₃$ had superior gas sensitivities.

Gas-Sensing Performance. Generally, the sensitivity of a gas-sensitive material to the target gas is strongly correlated with the working temperature. Therefore, we examined the relationship between the operating temperature and the capabilities of samples with different $Bi₂O₃$ loading ratios to detect 100 ppm of butanone (with or without UV illumination). The results are depicted in [Figure](#page-5-0) 8. In the temperature range of 75−225 °C, the gas sensitivities of all samples increased gradually with increases in the working temperature, irrespective of whether they were exposed to ultraviolet light. As the working temperature increased further, the responses of the gas sensors to butanone gradually decreased for all samples. According to literature reports, as the working temperature is increased, the amount of oxygen adsorbed on the surface gradually increases, leading to faster

Different Adsorption Sites on the Unloaded and Bi-Loaded
$SnO2(110)$ Surface

reactions between the target gas and the material surface. When the temperature exceeded the optimum operating temperature, the oxygen species on the surface of the material were desorbed, resulting in a decrease in the response.^{1[,18](#page-11-0)} In addition, we observed an interesting phenomenon. During irradiation with 365 nm UV light, the optimal working temperatures of the $Bi_{0.02}$ - $Sn_{0.98}O_2$ and $Bi_{0.03}$ - $Sn_{0.97}O_2$ samples decreased. This was attributed to the generation of photogenerated electron−hole pairs when the surface of the material was irradiated with UV light. The reactions between the holes and the adsorbed oxygen species increased the electron concentration within the material, which improved the gas sensitivity of the material.^{[25](#page-11-0)} After a comprehensive analysis, we concluded that 225 °C was the optimal working temperature. With the optimal working temperature, the $\text{Bi}_{0.02}\text{-}\text{Sn}_{0.98}\text{O}_2$ samples exhibited the highest responses in the dark or when exposed to UV radiation. Therefore, we selected pure $SnO₂$ and $Bi_{0.02}$ -Sn_{0.98}O₂ for the subsequent gas sensitivity study.

To evaluate the sensitivities of the two samples to various butanone concentrations, we carried out dynamic response− recovery tests. [Figure](#page-6-0) 9a,b shows the dynamic response− recovery curves for detection of 1−200 ppm butanone by the two sensors at their optimal operating temperature. It is evident that as the butanone gas concentration was increased, both sensor responses also increased. As the concentration in the system rose, the growth of the response values gradually decelerated. This was most likely attributable to saturation of the active sites on the surface of the material. Meanwhile, our findings indicated that the responses of the Bi containing

sensors were superior to that of pure $SnO₂$. After exposure to UV light, the sensor showed a significant enhancement in its ability to detect butanone at different concentration levels. Furthermore, when the gas concentration dropped to 1 ppm, even the sensor based on pure $SnO₂$ still provided a response of approximately 1.3 without UV light. This suggested that our synthetic sensing material had the capacity to detect low concentrations of butanone, with a detection limit of approximately 1 ppm.

The response−recovery time is a crucial parameter used in evaluating the rates for adsorption and desorption of the targeted gas from a sensor. The quicker the response and recovery times are, the more exceptional the performance of the sensor. This indicates the importance of real-time monitoring. The response−recovery curves for detection of 100 ppm butanone by the pure $SnO₂$ or $Bi_{0.02}$ - $Sn_{0.98}O₂$ at the optimal operating temperature and with or without UV light are depicted in [Figure](#page-6-0) 10a,b. Without exposure to UV light, the response time of the pure $SnO₂$ sensor was 22 s, and the recovery time was 35 s. The $Bi_{0.02}$ - $Sn_{0.98}O_2$ -based sensor exhibited a faster response time of 12 s and a shorter recovery time of 29 s. When exposed to UV light, the $SnO₂$ -based sensor exhibited a response time of 19 s and a recovery time of 26 s, and the $\rm{Bi_{0.02}}\rm{-}Sn_{0.98}O_2$ sensor had a response time of 10 s and a recovery time of 16. After thorough examination of the collected data, it was clear that the introduction of $Bi₂O₃$ into the surface of the material or exposing it to UV light resulted in substantial improvements in both the response and recovery times.

Stability refers to the capacity of a sensor material to resist external interference for a specified time. It is also an important parameter used to evaluate the capabilities of sensors in practical applications. We investigated the responses of the sensors containing pure SnO_2 and $Bi_{0.02}Sn_{0.98}O_2$ to 100 ppm butanone at the optimal working temperature for over a month, as shown in [Figure](#page-7-0) 11a. As shown in the graph, there was a gradual reduction in the sensor response as time progressed. This indicated that the sensitive material exhibited satisfactory stability. The reduced response was likely due to

Selectivity refers to the ability of a gas sensor to identify a specific gas within a mixture, and it is a crucial metric for evaluating the anti-interference performance. [Figure](#page-7-0) 12 shows the selectivities of the samples based on pure $SnO₂$ and $Bi_{0.02}$ - $Sn_{0.98}O₂$ in response to various VOCs at the optimal working temperature. We compared the responses of the two sensors when they were exposed to ethanol, acetone, butanone, formaldehyde, and toluene with or without UV light exposure. The graph shows that after the addition of $Bi₂O₃$ or exposure to UV light, the responses of the material to all VOCs were improved to varying extents. Despite this, it still exhibited a high response to butanone, indicating that the synthesized material had excellent selectivity.

fluctuations and could still maintain a high response.

[Table](#page-7-0) 1 summarizes the gas sensitivities of the $\mathrm{Bi}_{0.02}\mathrm{\cdot Sn}_{0.98}\mathrm{O}_2$ three-dimensional hierarchical structure and those of previously reported butanone gas sensors. From the table, it is evident that the sensor utilizing $Bi_{0.02}-Sn_{0.98}O_2$ exhibited better responses than most sensors. Therefore, we conclude that the sensor based on $\mathrm{Bi_{0.02}Sn_{0.98}O_{2}}$ has enormous potential for realtime butanone detection.

Gas-Sensing Mechanism. The gas-sensing mechanisms of n-type semiconductor materials (such as $SnO₂$) can be described with the spatial charge model.^{[44,50](#page-12-0)} When $SnO₂$ based sensors are exposed to air, oxygen is adsorbed on the surface. The adsorbed oxygen captures electrons from the $SnO₂$ conduction band and forms negatively charged oxygen ions on the material surface (O_2^-, O^-, O^{2-}) . As this progresses, the concentration of electrons in the $SnO₂$ conduction band gradually decreases, leading to the formation of a wider electron depletion layer on the material surface. This increases the resistance of the material. In our previous studies, we reported a close relationship between the types of oxygen anions and the temperature of the surrounding environment.^{[1](#page-10-0)} This can be shown as follows

$$
O_2(gas) \to O_2(ads) \tag{1}
$$

$$
O_2(ads) + e^- \rightarrow O_2^-(ads)(T < 100 \degree C)
$$
 (2)

$$
O_2^-(ads) + e^- \to 2O^-(ads)(100 \, ^\circ\text{C} < T < 300 \, ^\circ\text{C})\tag{3}
$$

$$
O-(ads) + e- \rightarrow O2-(ads)(T > 300 °C)
$$
 (4)

When reducing gases, such as butanone, are introduced into the system, they react with the adsorbed oxygen anions and release electrons back into the conduction band of the material. This reduces the thickness of the electron depletion layer and decreases the resistance of the material. The reaction is as follows 51

$$
CH_3COCH_2CH_3 + 110^- \approx 4H_2O + 4CO_2 + 11e^-
$$
\n(5)

Compared to the pure $SnO₂$ sensor, the $Bi₂O₃$ -loaded $SnO₂$ sensors exhibited significantly enhanced detection of butanone. Based on the literature, $SnO₂$ is a representative n-type semiconductor material with a band gap energy of 3.6 eV and a work function of 4.9 eV. On the other hand, Bi_2O_3 is also a

typical n-type semiconductor with a band gap energy of 2.8 eV and a work function of 5.04 eV.^{[52](#page-12-0),[53](#page-12-0)} Due to the lower work function of $SnO₂$ compared to $Bi₂O₃$, when these nanoparticles come into contact, the electrons serving as carriers migrate from $SnO₂$ to $Bi₂O₃$, resulting in a wider depletion layer on the $SnO₂$ surface. The resistance of the $SnO₂$ sensor loaded with $Bi₂O₃$ in air is significantly higher than the resistance of a pure $SnO₂$ sensor in air. When a $Bi₂O₃$ -loaded $SnO₂$ sensor is placed in a butanone atmosphere, more oxygen adsorbed on the material surface reacts with the butanone, releasing more electrons back into the conduction band and resulting in an enhanced sensitivity and stability of the sensor.⁵⁴

It was observed that gas sensing was significantly improved when the sensor was irradiated with UV light. According to literature reports, the surface of the material generates a substantial quantity of photogenerated electrons and holes under UV irradiation. The concentrations of O[−] species on the surface of sensing materials tend to increase. This process can be described as follows^{[55](#page-12-0)}

$$
O_2^- + e_{hv}^- \rightarrow 2O^- \tag{6}
$$

Additionally, the oxygen vacancy defects on the surface of the material also facilitate the formation of O[−] species. With this synergistic effect, the concentrations of O[−] species on the surface of the material are greatly increased, thus providing more active sites. When reducing gases are introduced into the system, many O[−] species participate in the oxidation reactions occurring on the surface, thereby enhancing the gas-sensing response. Moreover, exposure to UV light diminishes the activation energy of the surface oxidation reactions, resulting in reduced response–recovery times.^{[56](#page-12-0)}

Based on the above discussion, the synergistic mechanism for the effects of UV irradiation and $Bi₂O₃$ loading on the ability of $SnO₂$ to detect butanone is shown in [Figure](#page-7-0) 13.

First-principles calculations based on density functional theory have been widely used in determining the electronic structures of semiconductor materials.^{[57](#page-12-0)} In our study, we developed surface atomic models for $SnO₂$ with and without $Bi₂O₃$, as well as a model for butanone adsorption at various sites. These models were evaluated with first-principles calculations, ensuring accuracy and reliability of the simulations. The density functional theory computations were carried out with CASTEP and the ultrasoft pseudopotential.[58,59](#page-12-0) The exchange−correlation potential was determined with the Perdew−Burke−Ernzerhof (PBE) functional within the generalized gradient approximation (GGA) .⁶⁰ The cutoff energy for the plane-wave-basis expansion was set to 450 eV, and the convergence factors for the energy, force, and maximum displacement were 1.0×10^{-5} eV/atom, 3.0×10^{-2} eV/Å and 1.0 × 10[−]³ Å, respectively. The *k*-point grid sampling of the Monkhorst–Pack scheme was set as 2 × 2 × 1 in the irreducible Brillouin zone. The vacuum layer width was 15 Å. Meanwhile, the DFT-D correction method was used to describe the long-range van der Waals interactions. 61 As is widely known, the (110) surface of $SnO₂$ exhibited the highest thermal stability. Therefore, this paper was focused on the (110) surface of SnO₂ for research purposes. The optimized model is illustrated in [Figure](#page-8-0) 14.

The optimized model for $SnO₂(110)$ is illustrated in [Figure](#page-8-0) [14a](#page-8-0). We calculated the butanone adsorption energy for the samples with and without $Bi₂O₃$ loading. There were three sites for butanone adsorption on the surface of the material, Sn 5c (as shown in [Figure](#page-8-0) 14b,e), O 2c (as shown in [Figure](#page-8-0) 14c),

and Bi_2O_3 (as shown in [Figure](#page-8-0) 14d). The energy (E_{ab}) of butanone adsorption was defined as

$$
E_{ab} = E(sub + butanone) - E(sub) - E(butanone) \quad (7)
$$

where $E(\text{sub} + N_2)$ and $E(\text{sub})$ are the total energies of the system with and without butanone, respectively. *E*(butanone) is the total energy of butanone. [Table](#page-8-0) 2 presents the energies (*E*ab) for butanone adsorption at different adsorption sites on the unloaded and Bi-loaded $SnO₂(110)$ surface. The table shows that the adsorption energies for different sites on the pure $\text{SnO}_2(110)$ surface were −0.99 and −0.85 eV. With Bi₂O₃ loading, the adsorption energies at the different sites were −1.35 and −1.04 eV, respectively. The greater the adsorption energy is, the stronger the bonding between the gas and the material surface.^{[12](#page-11-0)[,62](#page-12-0)} Therefore, it can be inferred that when $Bi₂O₃$ was loaded on the surface of the $SnO₂$ material, the system showed enhanced adsorption of butanone. This effectively enhanced the ability of the material to detect butanone, which was consistent with our experimental results.

■ **CONCLUSIONS**

We have successfully synthesized $Bi₂O₃$ -loaded $SnO₂$ with a three-dimensional hierarchical structure using a combination of facile hydrothermal and impregnation precipitation methods. The gas-sensing tests conducted with butanone revealed exceptional performance under UV illumination, characterized by remarkable responses and response−recovery times (at 225 °C, the loaded sample achieved a response of 70, while the respective response−recovery times were 10 and 16 s). Moreover, our comprehensive physicochemical analyses revealed the key role of the unique hierarchical structure in facilitating efficient gas distribution. With the addition of $Bi₂O₃$, the surface of the sample showed a notable increase in reactive oxygen species (O[−]) following UV irradiation. Theoretical calculations have further elucidated the mechanism behind this enhancement, revealing that the introduction of $Bi₂O₃$ significantly enhances the material surface adsorption capacity for butanone, thus augmenting its gas-sensing performance. In summary, our findings underscore the pivotal role of $Bi₂O₃$ loading and UV exposure in enhancing the sensing capabilities of $SnO₂$, offering promising avenues for advanced gas-sensing applications.
