ABSTRACT

Objective: To compare faecal microbial composition in patients with systemic sclerosis (SSc) from 2 independent cohorts with controls and to determine whether certain genera are associated with SSc-gastrointestinal tract (GIT) symptoms.

Design: Adult patients with SSc from the University of California, Los Angeles (UCLA) and Oslo University Hospital (OUH) and healthy controls participated in this study (1:1:1). All participants provided stool specimens for 16S rRNA sequencing. Linear discriminant analysis effect size demonstrated genera with differential expression in SSc. Differential expression analysis for sequence count data identified specific genera associated with GIT symptoms as assessed by the GIT 2.0 questionnaire.

Results: The UCLA-SSc and OUH-SSc cohorts were similar in age (52.1 and 60.5 years, respectively), disease duration (median (IQR): 6.6 (2.5–16.4) and 7.0 (1.0–19.2) years, respectively), gender distribution (88% and 71%, respectively), and GIT symptoms (mean (SD) total GIT 2.0 scores of 0.7 (0.6) and 0.6 (0.5), respectively). Principal coordinate analysis illustrated significant microbial community differences between SSc and controls (UCLA: $p=0.001$; OUH: $p=0.002$). Patients with SSc had significantly lower levels of commensal genera deemed to protect against inflammation, such as *Bacteroides* (UCLA and OUH), *Faecalibacterium* (UCLA), *Clostridium* (OUH); and significantly higher levels of pathobiont genera, such as *Fusobacterium* (UCLA), compared with controls. Increased abundance of *Clostridium* was associated with less severe GIT symptoms in both cohorts.

Conclusions: The present analysis detected specific aberrations in the lower GIT microbiota of patients with SSc from 2 geographically and ethnically distinct cohorts. These findings suggest that GIT dysbiosis may be a pathological feature of the SSc disease state.

INTRODUCTION

The majority of patients with systemic sclerosis (SSc) experience gastrointestinal tract (GIT) dysfunction.^{1–2} Symptoms of lower

Summary box

What is already known about this subject?

- Gastrointestinal tract dysfunction affects over 90% of patients with systemic sclerosis.
- The pathogenesis of lower gastrointestinal tract dysfunction in systemic sclerosis is largely unknown.
- Emerging evidence suggest that gastrointestinal tract dysbiosis may be a feature of the systemic sclerosis disease state.

What are the new findings?

- The study found specific alterations in the gastrointestinal microbiota in two independent systemic sclerosis cohorts.
- The extent of dysbiosis (ie, alterations in the intestinal microbiota) appeared greatest in patients from the American systemic sclerosis cohort compared with those from the Norwegian systemic sclerosis cohort.
- Specific genera were associated with severity of gastrointestinal tract symptoms.

How might it impact on clinical practice in the foreseeable future?

- Currently, few effective treatment options exist for managing lower gastrointestinal tract symptoms in patients with systemic sclerosis. If specific genera are found to contribute the gastrointestinal tract phenotype in systemic sclerosis, such genera could provide specific targets for intervention to avert or treat this important clinical dimension of systemic sclerosis.

GIT involvement³ adversely affect quality of life and social functioning.^{4–5} Unfortunately, no effective treatment options exist for eliminating these disruptive symptoms, largely because the pathogenesis of this dimension of SSc is poorly understood.

GIT dysbiosis occurs in a number of chronic inflammatory conditions, including inflammatory bowel disease (IBD),^{6–9} and

recent studies suggest that alterations in GIT microbiota may be a feature of the SSc disease state.^{3, 10} Our prior study demonstrated that patients with SSc had decreased abundance of beneficial human commensal genera known to produce key energy metabolites and anti-inflammatory molecules for mucosal health (eg, *Faecalibacterium*; *Clostridium*) with a concurrent increase in potential pathobiont genera (eg, invasive γ *Proteobacteria*; *Fusobacterium*), compared with controls.¹⁰

This study also demonstrated that increased abundance of *Clostridium* and decreased abundance of *Fusobacterium* were independently associated with decreased GIT symptoms.¹⁰ To further explore whether alterations in microbial composition may serve as a pathogenic factor in SSc-GIT dysfunction, the present study examined the lower GIT microbiota from two independent SSc cohorts. Whereas our prior study examined colonic mucosal microbes via colonoscopy, the present study examined stool specimens from the same patients with SSc.¹⁰ Assessment of stool specimens may reflect other aspects of the gut microbiota (eg, metabolic features) and can be obtained by a less invasive approach.

The objectives of this study, not previously explored in the SSc literature, were to: (1) establish whether analysis of stool specimens can distinguish the GIT microbiota of patients with SSc versus healthy controls; (2) compare the GIT microbiota of patients with SSc from two geographically independent cohorts; and (3) evaluate the hypothesis that specific microbial genera are associated with SSc-GIT symptom severity.

MATERIALS AND METHODS

Study participants

Patient participants were consecutively enrolled from the outpatient rheumatology clinics at University of California, Los Angeles (UCLA) and Oslo University Hospital (OUH). Eligible participants included adult (≥ 18 years) patients with SSc according to the 2013 American College of Rheumatology/European League Against Rheumatism Classification Criteria for SSc.¹¹ Exclusion criteria included IBD, inability to withstand from taking an antibiotic and a probiotic for at least 3 weeks prior to the stool collection. Patients were allowed to continue taking a proton pump inhibitor medication because this agent exerts negligible effects on colonic microbiota.¹²

Healthy controls stool specimens were obtained from the UCLA Specialized Center of Research in Neurovisceral Sciences and Women's Health Repository, which consists of stool specimens from healthy adult participants (12 men and 9 women) who do not have GIT symptoms. These control participants were different than the control participants used in our prior study.¹⁰ We attempted to match 17 of these healthy participants by age and sex with the UCLA-SSc cohort patients (1:1); however, the healthy control cohort had more men than

women so gender matching was not always possible. These healthy controls specimen also served as the controls for the OUH-SSc cohort.

The UCLA Institutional Review Board and the Regional Committee of Health and Medical Research Ethics in Norway approved the study protocol and written informed consent was obtained from each participant.

Specimen procurement and processing

Participants at both sites collected stool specimens using our previously published, standard collection method¹³ and immediately froze the specimen. Frozen specimens were subsequently transferred on ice to the participant's study centre and stored at -80°C . OUH specimens were shipped overnight on dry ice to UCLA for further processing. Please see the online supplementary appendix for complete details of specimen procurement and processing.

16S rRNA gene sequencing and microbial composition analysis

The microbiota from the stool specimens were profiled by multiplex sequencing for bacterial rRNA genes using an Illumina HiSeq 2500 (Illumina, San Diego, California, USA) sequence technique. All samples (UCLA-SSc, OUH-SSc, controls) were analysed simultaneously at UCLA to avoid any batch effects. The exact details of this approach have been outlined in our prior publication,^{9, 10} and are summarised in the online supplementary appendix.

Faecal calprotectin

Faecal calprotectin concentrations were measured in duplicate from the stool specimens of the UCLA-SSc and healthy control participants using a commercial kit (KTR-849, Epitope Diagnostics, San Diego, California, USA) according to the manufacturer's instructions.

Assessment of GIT symptoms

On the day of their stool collection, the UCLA and OUH-SSc participants completed the GIT 2.0, a valid measure of GIT symptom severity in patients with SSc.¹⁴ The questionnaire consists of seven domains and has been translated and validated in several languages, including Norwegian. scores on the GIT 2.0 can indicate self-rated severity (ie, none/mild vs moderate vs severe/very severe disease) of GIT involvement based on previously published score thresholds.¹⁴

Statistical and bioinformatics analyses

Statistical approach

Analyses were performed using R V.3.1.2. Mean and SDs were used to describe continuous parametric data; median and IQRs were used to describe continuous non-parametric data. All tests were two-sided with a 0.05 α level. To compare the microbial communities of SSc versus control samples, α and β diversity were analysed. The α diversity represents the complexity of composition within members of a group, and β diversity represents

the between-participant similarity of microbial composition and enables the identification of differences between samples within a group. We also examined taxonomic differences at specific levels (ie, phylum, genus) using linear discriminant analysis effect size (LefSe). We used the false discovery rate (FDR) of Benjamini and Hochberg,¹⁵ and a significant association was defined at the FDR q-value ≤ 0.1 . Please see the online supplementary appendix for further details.

RESULTS

Participant characteristics

Seventeen UCLA-SSc cohort patients (88% women; median age 52.1 years) and 17 OUH-SSc cohort patients

(71% women; median age 60.5 years) were enrolled (table 1). The healthy control cohort (N=17) was younger than the SSc cohorts (median age 29.0 years), and had a predominance of women (60% women). The OUH-SSc cohort was mostly Caucasian (94%); whereas the UCLA-SSc and healthy control cohorts had more Hispanics (35% and 24%, respectively, vs 6% in the OUH-SSc cohort). The mean body mass index (BMI) was similar in the two SSc cohorts (~24 for both cohorts) and slightly higher in the controls (28.1), although the difference in BMI between SSc participants and healthy controls was not significant.

UCLA-SSc and OUH-SSc cohort patients had similar SSc disease durations, proportion of patients with diffuse cutaneous sclerosis, and autoantibody profiles (table 1).

Table 1 SSc participant characteristics

	UCLA-SSc participants (N=17)	OUH-SSc participants (N=17)
Age (years)	Median 52.1 (IQR 46.6–63.0)	60.5 (IQR 46.0–71.0)
Female	15 (88.2%)	12 (70.6%)
Race

Constipation	Mean 0.7 (0.7)§	Mean 0.6 (1.1)§
Emotional well-being	Mean 0.5 (0.7)§	Mean 0.5 (0.7)§
Social functioning	Mean 0.5 (0.5)§	Mean 0.4 (0.6)¶

Values are n (%), except where otherwise noted.

*Dosages of prednisone were ≤ 10 mg daily.

†Immunosuppressant medications used included mycophenolate (UCLA: N=1; OUH: N=2) and azathioprine (UCLA: N=2).

‡Probiotic used in the UCLA-SSc cohort included culturelle (N=1), florify (N=1) and align (N=1). For the OUH-SSc cohort, patients consumed probiotic enriched sour milk products (N=3). Probiotics were not consumed within 3 weeks of the stool collection.

§Score indicates moderate symptom severity.¹⁴

¶Score indicates mild symptom severity.¹⁴

ANA, anti-nuclear antibody; BMI, body mass index; DLCO, diffusing capacity for carbon monoxide; GIT, gastrointestinal tract; HRCT, high-resolution CT; MRSS, Modified Rodnan Skin Score; OUH, Oslo University Hospital; SSc, systemic sclerosis; UCLA, University of California, Los Angeles.

However, more patients in the UCLA-SSc cohort (71%) had clinically significant interstitial lung disease (ILD) by high-resolution CT,¹⁶ compared with the OUH-SSc cohort (47%).

The UCLA-SSc and OUH-SSc cohorts also had similar GIT symptom profiles (table 1). The mean GIT 2.0 scores indicated moderate symptom severity¹⁴ for the total score, as well as for the following domains: distension/bloating, emotional well-being and constipation (table 1). The mean GIT 2.0 scores for faecal soilage and diarrhoea indicated mild symptom severity¹⁴ (table 1). Six UCLA-SSc participants (35%) had taken antibiotics in the 3 months preceding stool collection; the mean time between cessation of antibiotics and stool collection was 6.5 weeks (range 4–12 weeks). None of the OUH-SSc cohort patients had taken antibiotics 3 months prior to stool sampling.

Only three of the UCLA-SSc cohort patients had elevated levels of faecal calprotectin, which was defined as >50 µg/g. None of the control participants had elevated levels of faecal calprotectin.

Colonic microbial diversity in SSc

After the operational taxonomic unit (OTU) selection process, a total of 231, 250 and 184 species-level OTUs were generated from the UCLA-SSc, OUH-SSc and healthy control cohorts, respectively. The α diversity (ie, the complexity of microbial composition) was similar between the UCLA-SSc and control participants (see online supplementary figure S1) and between the OUH-SSc and control participants (see online supplementary figure S2). There were also no significant differences in α diversity between the UCLA-SSc and OUH-SSc participants (see online supplementary figure S3).

Figure 1 Significant differences in the β diversity of the SSc and healthy samples as demonstrated by principal coordinate analysis plots of the weighted UniFrac distance. Each dot represents a sample from a UCLA-SSc cohort patient (open circle) or a healthy control (closed circle). Each star represents a sample from a OUH-SSc cohort patient. The p values provided were calculated by analysis of variance using distance matrices. OUH, Oslo University Hospital; PCoA, principle coordinate analysis; SSc, systemic sclerosis; UCLA, University of California, Los Angeles.

The β diversity was then computed to determine whether SSc and control participants differed in their microbial composition. The principle coordinate analysis visualisation of the weighted UniFrac distances and analysis of variance using distance matrices (Adonis) of this comparison are shown in figure 1. In the UCLA-SSc (R^2 0.355; $p=0.001$) and the OUH-SSc (R^2 0.126; $p=0.002$) cohorts, the microbial composition among patients with SSc was significantly different than healthy controls. The magnitude of this difference appeared greater between the UCLA-SSc cohort and healthy controls than between the OUH-SSc cohort and healthy controls based on the R^2 values and as illustrated in figure 1. The β diversity also differed between the UCLA-SSc and OUH-SSc cohort patients (R^2 0.145; $p=0.002$).

Colonic microbial genera are differentially abundant in patients with SSc

To begin to define the compositional differences between patients with SSc and healthy controls predicted by the β diversity analysis, the relative abundances of microbial composition at different taxonomic levels were computed (figure 2). The two predominant phyla in SSc samples were *Bacteroidetes* (UCLA: 21.3%; OUH: 45.0%; controls: 63.2%), and *Firmicutes* (UCLA: 63.5%; OUH: 42.8%; controls: 33.0%). The relative abundance of *Bacteroidetes* was significantly decreased in the UCLA-SSc cohort compared with the healthy control cohort ($p<0.0001$) and in the OUH-SSc cohort compared with the healthy control cohort ($p=0.009$).

LefSe multivariate analysis demonstrated significant taxonomic differences between SSc and healthy controls at the genus level for the UCLA-SSc (figure 3) and OUH-SSc (figure 4) cohorts. The LefSe analysis comparing the UCLA-SSc and healthy control cohorts yielded

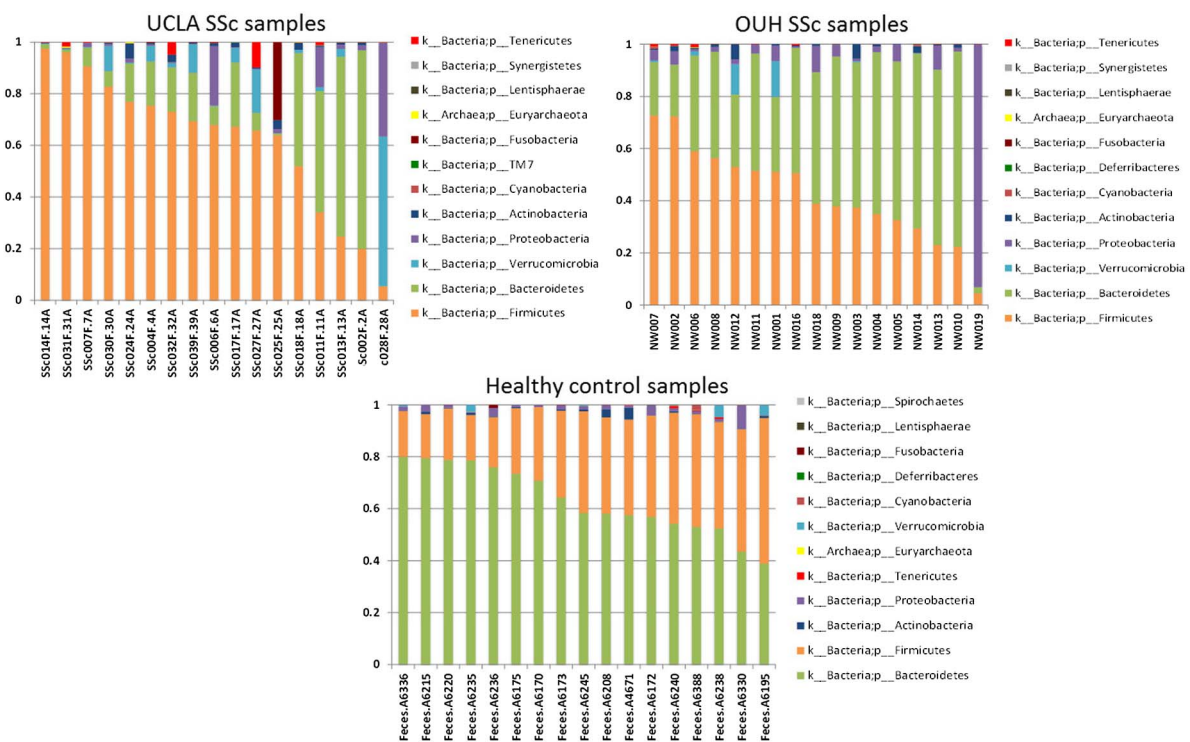

Figure 2 Microbial composition at the phylum level in UCLA-SSc samples (top left), OUH-SSc samples (top right) and healthy samples (bottom left). Legend provides colour coding specific to each phylum. OUH, Oslo University Hospital; SSc, systemic sclerosis; UCLA, University of California, Los Angeles.

more significant genus-level differences than the analysis comparing the OUH-SSc and healthy control cohorts.

Commensal genera such as *Faecalibacterium* (UCLA), *Clostridium* (OUH) and *Bacteroides* (UCLA, OUH) were depleted in patients with SSc; whereas, *Fusobacterium* (UCLA), *Ruminococcus* (UCLA) and the uncommon γ -*Proteobacteria*, *Erwinia* (UCLA), were enriched in patients with SSc, compared with health controls. Consistent with our prior study,¹⁰ *Lactobacillus* (considered to be a commensal genus¹⁷) was found in greater abundance in patients with SSc compared with controls in the UCLA and OUH cohorts (figures 3 and 4).

When comparing the UCLA-SSc and OUH-SSc cohorts, the LefSe analysis revealed that specific commensal genera, including *Faecalibacterium* and *Bacteroides*, were significantly more abundant in the OUH-SSc cohort patients compared with the UCLA-SSc cohort patients (fold change scores of 4.85 and 3.75, respectively).

Specific microbial genera and species are associated with SSc-GIT symptoms

Differential expression analysis for sequence count data multivariate analysis identified specific microbial genera associated with SSc-GIT symptom severity based on the scores for the total GIT 2.0 and individual domains (eg, constipation, diarrhoea or distension/bloating). For the total score and each domain, patients were dichotomised into low (none-to-mild) or high (moderate-to-severe) GIT symptom severity groups, and the fold change and *p*-values for organisms reaching significance were

tabulated (see online supplementary table S1). The frequency of distribution of patients in each disease severity category were fairly well balanced (N for low vs high groups): total score (18 vs 16); constipation (16 vs 18); distention/bloating (8 vs 26) and diarrhoea (18 vs 15).

In both SSc cohorts, *Clostridium* was more abundant in patients with low GIT symptom severity (for the total GIT score and the bloating/distension domain) compared with patients with high GIT symptom severity (figure 5 and see online supplementary table S1). *Lactobacillus* was more abundant in patients with none-to-mild constipation compared with patients with moderate-to-severe constipation. In contrast, *Prevotella* was more abundant in patients with moderate-to-severe GIT symptom severity (bloating/distention domain, diarrhoea domain) compared with patients with none-to-mild GIT symptom severity.

DISCUSSION

Consistent with our prior findings,¹⁰ the present study demonstrated that the SSc disease state is associated with alterations in the GIT microbial consortium. Using data from two independent SSc cohorts, we found that specific faecal microbial taxa were enriched or depleted among patients with SSc compared with healthy controls. We also demonstrated that specific taxa were associated with severity of GIT symptoms in both SSc cohorts.

In terms of phylum-level differences, the relative abundance of *Bacteroidetes* was significantly decreased in the

Figure 3 Genus-level taxa associated with UCLA-SSc cohort patients versus healthy participants. LefSe multivariate analysis was used to identify significant associations ($q < 0.1$), and LDA was used to calculate the effect size for these associations. Negative and positive effect sizes denote genera decreased (blue) or increased (red) in patients with SSc, respectively. All genera with an absolute LDA score > 2.5 were included in this figure. LDA, linear discriminant analysis; LefSe, linear discriminant analysis effect size; SSc, systemic sclerosis; UCLA, University of California, Los Angeles.

Figure 4 Genus-level taxa associated with OUH-SSc cohort patients versus healthy participants. LefSe multivariate analysis was used to identify significant associations ($q < 0.1$), and LDA was used to calculate the effect size for these associations. Negative and positive effect sizes denote genera decreased (blue) or increased (red) in patients with SSc, respectively. All genera with an absolute LDA score > 2.5 were included in this figure. LDA, linear discriminant analysis; LefSe, linear discriminant analysis effect size; OUH, Oslo University Hospital; SSc, systemic sclerosis.

UCLA and OUH-SSc cohorts compared with the healthy control cohort. This finding is of interest in light of the recent evidence suggesting that the ratio of *Firmicutes* to *Bacteroidetes* may have an important effect on human

health.^{18 19} Patients with SSc in the UCLA cohort had the lowest proportion of *Bacteroidetes* (21.3%), followed by patients with SSc in the OUH cohort (45.0%) and healthy controls (63.2%).

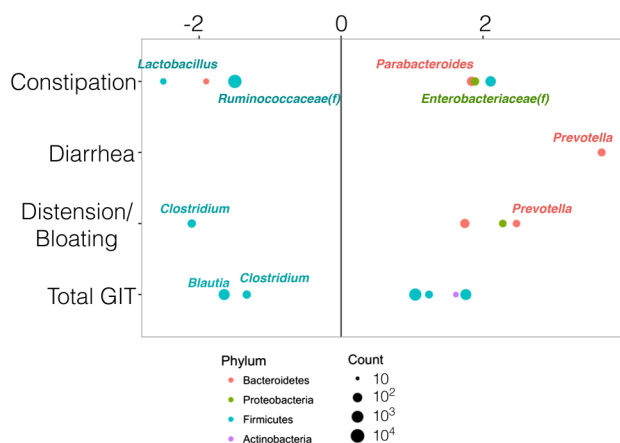

Figure 5 Bacterial taxa associated with GIT disease score and domains. Patients were dichotomised into low (none-to-mild) or high (moderate to severe) disease severity groups for the total GIT 2.0 score and its individual domains (constipation, diarrhoea or distension/bloating). DESeq2 multivariate analysis was used to identify microbial taxa significantly associated with low versus high groups (online supplementary table S1), and calculate the fold change between groups. Negative fold change scores (log₂) denote organisms decreased in high disease severity groups; whereas, positive fold change scores denote organisms increased in high disease severity groups. Legend provides colour code of bacterial taxa at the phylum level; ‘f’ denotes family-level taxa. The size of the coloured dots represents the square root of the absolute mean counts of the OTUs at the genus level. DESeq2, differential expression analysis for sequence count data; GIT, gastrointestinal tract; OUT, operational taxonomic unit.

Consistent with the observed decrease in *Bacteroidetes*, lower level taxonomic analysis revealed that both SSc cohorts had significantly lower levels of the commensal genera *Bacteroides*, which is thought to protect the host from mucosal inflammation and against colonisation of pathogenic species. Low relative abundance of *Bacteroides* is associated with increased disease activity in other chronic inflammatory diseases, such as Crohn’s disease (CD).²⁰ The fold change scores for the UCLA-SSc and OUH-SSc cohorts relative to controls was nearly 5 signifying a substantial shift in this genus in the SSc disease state.

Concordant with our prior study using colonic lavage specimens,¹⁰ we found that *Faecalibacterium* (UCLA) and *Clostridium* (OUH) were also depleted in SSc. Low abundance of these genera is associated with increased disease activity in IBD.^{21–23} As *Clostridium* species have been found to induce the expansion of regulatory T cells,²⁴ it is tempting to speculate that depletion of these taxa may reduce the number of regulatory T cells, which may play a role in SSc pathogenesis.²⁵ It is important to note, however, that species within this genus vary in terms of their metabolic properties. Future studies may explore the relationship between the abundance of specific species within the *Clostridium* genus and levels of circulating regulatory T cells.

In line with the potential immunoregulatory properties of *Clostridium*, we found that increased abundance of this genus was associated with decreased GIT symptoms (for the total GIT symptom severity score and the bloating/distension domain score). Our prior study also reported a link between *Clostridium* and GIT symptoms.¹⁰ If future studies demonstrate that *Clostridium* attenuates local or systemic inflammation in SSc (through effects on T regulatory cells), therapy aimed at increasing the abundance or activity of species in this genus may improve SSc disease activity.

In contrast, *Prevotella* was more abundant in patients with more severe GIT symptoms (bloating/distention domain, diarrhoea domain scores). This genus appears to have effects on intestinal T helper 17 cells,²⁶ and it has been found to be increased in faecal samples from patients with CD,^{27–28} and new-onset rheumatoid arthritis.²⁹

Also consistent with our prior study, the abundance of the pathobiont genera, *Fusobacterium*, and uncommon γ -*Proteobacteria* (eg, *Erwinia*) were higher in the UCLA-SSc faecal samples compared with controls. *Fusobacterium* species are increased in patients with CD compared with healthy controls and have been mechanistically proven to enhance proinflammatory responses.^{30–31}

We are intrigued by the increase of *Lactobacillus* in the UCLA-SSc and OUH-SSc cohorts compared with healthy controls. This finding has been observed now in three different SSc cohorts (UCLA (colonic lavage specimens, faecal specimens), OUH (faecal specimens), Swedish cohort (faecal specimens)).^{10–32} We do not attribute this expansion to probiotic use. First, due to the exceptionally larger scale of the intestinal microbiome, ingestion of lactobacillus-bearing probiotics does not measurably alter faecal microbial composition.³³ Second, very few patients in the present cohorts were taking probiotics on a regular basis, and none were taking probiotics within 3 weeks of the stool collection. Deemed a beneficial commensal genus by several host inflammatory and physiological end points in animal models, its abundance is typically reduced in chronic inflammatory human diseases.³⁴ We further note that members of this genus and their products alter the broader intestinal microbial ecosystem gene expression and function, which may be an intermediary of their action on systemic host phenotypes.^{33–35} Since many patients with SSc consume commercial probiotic supplements that commonly include *Lactobacillus* species, the utility of *Lactobacillus* as a biomarker or potential intervention in patients deficient for this genus warrants further study.

The overall extent of dysbiosis appeared greatest in the patients with SSc from UCLA compared with patients with SSc from the OUH cohort. Possible explanations for this disparity include different SSc phenotypes between the cohorts. For instance, more patients with SSc in the UCLA cohort had ILD than in the OUH cohort. Accumulating evidence suggests that GIT microbiota plays a central role in regulating immune

responses in pulmonary disease, such as asthma.³⁶ It is possible that patients with SSc-ILD have distinct microbiota features compared with patients with SSc without ILD. Indeed, a recent analysis by Andréassen *et al*³² found that among patients with SSc from a single-centre cohort, the extent of GIT dysbiosis was more severe in patients with ILD compared with patients without ILD. Furthermore, although there was a similar ratio of patients with diffuse versus limited cutaneous disease in each SSc cohort, there may have been subtle differences in the peak severity of cutaneous sclerosis between the two cohorts.

In addition to SSc disease phenotype, genetic variation may account for some of the observed differences in severity of dysbiosis between the two SSc cohorts. The majority of the OUH-SSc cohort was Caucasian with a genetic Norwegian background; whereas the UCLA cohort was more ethnically diverse. A study for ulcerative colitis reported that ethnicity stratifies a small proportion (7.5%) of observed variation in β diversity.³⁷ Dietary variation may also contribute to the differences observed between the two SSc cohorts.

In contrast with a prior research,^{32 38} faecal calprotectin concentrations were not elevated in the majority of patients with SSc (from the UCLA cohort), although different kits/protocols may have been used in prior studies. While accumulating evidence suggests that faecal calprotectin is seen in inflammatory intestinal diseases (eg, IBD, colorectal cancer), future studies are needed to determine whether this protein is a marker of disease activity or the extent of dysbiosis in SSc.

The findings of the present study should be considered within the context of certain limitations. First, the present study is cross-sectional. It is unclear whether the relationships observed between specific genera and GIT symptoms are causal and/or persist with time. Second, the sample size for both SSc cohorts is small. Despite the small sample size, we observed several significant associations consistent with the associations reported in our prior study,¹⁰ suggesting that the present findings are unlikely to be due to chance alone. Third, the same healthy control cohort was used for the UCLA and OUH-SSc cohorts. It may have been more ideal to use a Norwegian healthy control cohort for the OUH-SSc analyses to control for genetic and dietary variation.

In addition, it may be prudent to include a measure of GIT transit in future SSc-GIT microbiome studies. This study did not assess GIT transit as there is no valid measure of GIT transit in SSc; however, diarrhoea and constipation are intrinsically related to GIT transit. Future studies of this nature may consider using potential surrogate measures of GIT transit, such as wireless capsule endoscopy. Finally, although it is a challenge to quantify dietary patterns due to patient recall bias, future studies could also consider the impact of diet on microbial composition in SSc. Accordingly, a distinct study design will be required to assess the differential microbiota associated with disease state or phenotypic progression.

The present study also has important strengths. By studying two independent SSc cohorts, we have minimised the risk of type 1 error that often ensues in discovery cohort analyses of this nature. In addition, by performing all of the sequencing analyses simultaneously, we have eliminated the possibility of a batch effect. We also took substantial caution to ensure that all patients withheld medications, such as antibiotics and probiotics, at least 3 weeks prior to the stool collection, by verifying medication lists three times in the month preceding the collection.

To conclude, this study identified bacterial genera associated with SSc using sophisticated sequencing analyses of faecal specimens. Many of the genus-level gains and losses appreciated in the faecal specimens examined in the present study were also observed in our prior study using colonic-mucosal specimens from the same patients with SSc (but different control patients).¹⁰ Using two independent SSc cohorts, this study also uncovered relationships between specific genera and severity of SSc-GIT symptoms, which merit further investigation. While larger studies are needed to validate and expand on these findings, the present study is the first to characterise the lower GIT microbiota in two geographically and ethnically distinct SSc cohorts.

Y-LC provided substantial contributions to study conception and design; analysis and interpretation of the data; revising the manuscript critically for important intellectual content; approval of the final manuscript. JPJ, KT, EAM and PJC provided substantial contributions to study conception and design; revising the manuscript critically for important intellectual content; approval of the final manuscript. JRH, MK and ØMi provided substantial contributions to the analysis and interpretation of data; revising the manuscript critically for important intellectual content; approval of the final manuscript. VL provided substantial contributions to the analysis and interpretation of data; analysing the biospecimens; revising the manuscript critically for important intellectual content; approval of the final manuscript. LC, JL and ØMo provided substantial contributions to the analysis and interpretation of data; revising the manuscript critically for important intellectual content; approval of the final manuscript. JB provided substantial contributions to study conception

and design, the analysis and interpretation of data; revising the manuscript critically for important intellectual content; approval of the final manuscript.

Funding This work was supported by grants from CURE: Digestive Disease Research Center supported by NIH grant P30DK41301—Pilot and Feasibility (ERV); NIH PO-1 DK46763 (JB) and UL1TR001881 (JB); The Unger-Vetlesen Foundation (A-MH-V); The Norwegian Women's Public Health Association (A-MH-V); Iris Cantor-UCLA Women's Health Center Executive Advisory Board (KT); NCATS UCLA CTSI UL1TR000124 (KT); NIH P50 DK064539 (EAM); Health Authority of South-Eastern Norway 2016067 (MK); and Norwegian Research Council 240787/F20 (JRH).

Disclaimer The views expressed in the submitted article are the authors' own and not an official position of the institution or funder.

Competing interests None declared.

Ethics approval UCLA Institutional Review Board (IRB) and the Regional Committee of Health and Medical Research Ethics in Norway.

Provenance and peer review Not commissioned; externally peer reviewed.

Data sharing statement No additional data are available.
