21

## 22 **Abstract**

23 The systemic nature of SARS-CoV-2 infection is highly recognized, but poorly characterized. A  
24 non-invasive and unbiased method is needed to clarify whole body spatiotemporal dynamics of  
25 SARS-CoV-2 infection after transmission. We recently developed a probe based on the anti-  
26 SARS-CoV-2 spike antibody CR3022 to study SARS-CoV-2 pathogenesis *in vivo*. Herein, we  
27 describe its use in immunoPET to investigate SARS-CoV-2 infection of three rhesus macaques.  
28 Using PET/CT imaging of macaques at different times post-SARS-CoV-2 inoculation, we track the  
29 <sup>64</sup>Cu-labelled CR3022-F(ab')<sub>2</sub> probe targeting the spike protein of SARS-CoV-2 to study the  
30 dynamics of infection within the respiratory tract and uncover novel sites of infection. Using  
31 this method, we uncovered differences in lung pathology between infection with the WA1  
32 isolate and the delta variant, which were readily corroborated through computed tomography  
33 scans. The <sup>64</sup>Cu-CR3022-probe also demonstrated dynamic changes occurring between 1- and  
34 2-weeks post-infection. Remarkably, a robust signal was seen in the male genital tract (MGT) of  
35 all three animals studied. Infection of the MGT was validated by immunofluorescence imaging  
36 of infected cells in the testicular and penile tissue and severe pathology was observed in the  
37 testes of one animal at 2-weeks post-infection. The results presented here underscore the  
38 utility of using immunoPET to study the dynamics of SARS-CoV-2 infection to understand its  
39 pathogenicity and discover new anatomical sites of viral replication. We provide direct evidence  
40 for SARS-CoV-2 infection of the MGT in rhesus macaques revealing the possible pathologic  
41 outcomes of viral replication at these sites.

## 42 Introduction

43           The COVID-19 pandemic has exposed the broad systemic impact that can be caused by  
44 infection with a respiratory virus. Disease associated with SARS-CoV-2 infection starts with  
45 respiratory pathologies and subsequently can extend to other organ systems. There is now  
46 ample evidence that SARS-CoV-2 can disseminate and replicate in tissues beyond the  
47 respiratory tract. A clear example is infection in the gastrointestinal (GI) tract<sup>1</sup>. GI symptoms,  
48 including diarrhea, have been reported by individuals with mild COVID-19, and hospitalized  
49 patients have exhibited more severe symptoms such as ischemia and GI bleeds<sup>2, 3, 4</sup>. In addition,  
50 it is now well established that virus is shed through the GI tract in most infected individuals and  
51 wastewater screening has become an important tool for disease surveillance<sup>5, 6</sup>. Although less  
52 studied, many other tissues have been found to harbor SARS-CoV-2. Multiple groups have  
53 shown the presence of viral RNA in cardiac, renal, and brain tissues<sup>7-10</sup>. There is also some  
54 evidence of virus in the male genital tract (MGT)<sup>11, 12</sup>. Furthermore, symptoms associated with  
55 all these organ systems have been regularly reported<sup>13</sup>. Likewise, other RNA viruses have  
56 documented early dissemination to distal tissues that manifest infection-related pathology over  
57 the long term, including (but not limited to) polio, mumps, Ebola virus, Zika virus, and SARS-  
58 CoV-1<sup>14, 15</sup>. For example, studies of autopsy tissue from fatalities of SARS-CoV-1 suggested that  
59 it causes inflammation of the testes (orchitis)<sup>15</sup>.

60           However, it is not yet clear if the diverse pathologies associated with SARS-CoV-2  
61 infection are due to secondary effects of systemic inflammation or direct infection of tissues at  
62 these distal sites. Human studies have relied on biopsies and autopsy samples to investigate  
63 viral replication in sites other than the respiratory tract. The biopsy/autopsy samples only offer

64 a snapshot of the *in vivo* dynamics of disease, and there are ethical and technical difficulties in  
65 obtaining them. Using animal models of infection allows for a more thorough collection and  
66 investigation of affected tissues. To gain critical insights into systemic infection by SARS-CoV-2,  
67 new animal models are needed to determine the extent of disseminated infection and its  
68 relationship to pathogenesis.

69 SARS-CoV-2 infection in the non-human primate (NHP), rhesus macaques (*Macaca*  
70 *mulatta*), recapitulates mild to moderate human disease<sup>16-18</sup>. Infected macaques exhibit viral  
71 shedding through the respiratory tract and viral pneumonia similar to the mild form seen in  
72 humans. The architecture of the respiratory tract is also generally conserved between humans  
73 and macaques making them an ideal model for studying SARS-CoV-2 infection. Infection of  
74 other organ systems has also been observed in macaques, most commonly in the GI tract<sup>19, 20</sup>.  
75 To gain insights into the spatiotemporal dynamics of SARS-CoV-2 during infection in the rhesus  
76 macaque model, we adapted an immunoPET methodology that we are currently using to study  
77 various aspects of simian immunodeficiency virus (SIV) acquisition and pathogenesis<sup>21</sup>.  
78 ImmunoPET is a molecular imaging technique that combines the specificity of an antibody-  
79 based probe labeled with a radioisotope with the *in vivo* imaging power of combined positron  
80 emission tomography-computed tomography (PET/CT). ImmunoPET was originally developed  
81 and has been widely used in cancer research. Recently, with the advent of new antibodies and  
82 better radioisotopes, immunoPET has been extended to studying many other biological  
83 processes, including the *in vivo* dynamics of pathogens<sup>22, 23</sup>. ImmunoPET allows for repeated  
84 and specific imaging of virally infected cells *in vivo* by using a radioisotope labeled antibody  
85 targeting a viral protein. The non-invasive nature of PET/CT imaging allows for unbiased

86 discovery of novel tissue sites of infection through whole body imaging. Furthermore, the cell-  
87 associated PET signal persists in tissue allowing for a radioactive probe-guided necropsy to help  
88 determine the precise location of infected cells.

89 We have previously reported the early development of an *in vivo* antibody-based probe  
90 against SARS-CoV-2 utilizing fluorescent tagging of the F(ab')<sub>2</sub> of the anti-spike IgG CR3022<sup>24</sup>.  
91 CR3022 was one of the first monoclonal antibodies identified that bound tightly to SARS-CoV-2.  
92 It was originally derived from an individual infected with SARS-CoV-1 but also exhibits tight  
93 binding to the spike protein of SARS-CoV-2. Here, we extend the use of the F(ab')<sub>2</sub> of the anti-  
94 spike IgG CR3022 labelled with copper 64 (Cu<sup>64</sup>) for immunoPET and targeted necropsy to study  
95 systemic SARS-CoV-2 infection in the rhesus macaque model. Our results show the utility of this  
96 approach in investigating SARS-CoV-2 pathogenesis in the respiratory tract and in uncovering  
97 novel anatomical sites of infection. Interestingly, we detected a robust and dynamic signal in  
98 the MGT including the prostate, penis, and testicles. This observation is consistent with  
99 emerging and ongoing clinical observations of orchitis, oligo-/azoospermia, and erectile  
100 dysfunction, and reveals these comorbidities are likely a consequence of the direct viral  
101 infection of the tissues of the MGT. The successful development of an immunoPET probe to  
102 study SARS-CoV-2 in the rhesus macaque challenge model will allow longitudinal studies to gain  
103 insights into SARS-CoV-2 progression, dissemination, and the development of comorbidities.

104

## 105 **Results**

### 106 **Description of macaque studies and PET/CT-guided necropsy**

107 The basic process and workflow of the PET/CT guided necropsy method is shown in Fig 1A. The  
108 PET/CT guided necropsy approach consists of three separate PET/CT scans that are used to map  
109 probe signal at the whole animal, organ, and tissue levels. The first scan is typically ~16-24  
110 hours after the injection of the radio labelled F(ab')<sub>2</sub> probe allowing for movement into the  
111 tissues<sup>21</sup>. This whole-body PET/CT scan (Scan 1) identifies “hot” organs and tissue areas. These  
112 tissue areas are collected at necropsy immediately following the scan and subjected to a second  
113 PET/CT scan (Scan 2). Tissues containing probe signal are cut into small blocks, placed in  
114 cryomolds, and then rescanned (Scan 3) to identify individual “hot” tissues/blocks that likely  
115 contain foci of virally infected cells. These “hot” tissues can then be used for downstream  
116 characterization including RNA quantification and different types of microscopic analyses  
117 characterizing virally infected cells.

118 The SARS-CoV-2 pilot infection study design with 3 male rhesus macaques is shown in  
119 Fig 1B. Based on our previous studies utilizing a fluorescently tagged F(ab')<sub>2</sub> probe, we decided  
120 to perform the first PET/CT scan 1 week after challenge. In the first study, we infected a male  
121 rhesus macaque (LP14) with the WA1 isolate of SARS-CoV-2 and performed a single PET/CT  
122 scan followed immediately by necropsy. In the second study, two male rhesus macaques were  
123 infected with the Delta variant of SARS-CoV-2, and both underwent a PET/CT scan 1 week after  
124 infection. One of the animals (IN22) was scanned twice after a single probe injection and  
125 necropsied after the 2<sup>nd</sup> scan. The early scan of IN22 was done 3 hours after injection of the  
126 <sup>64</sup>Cu-labelled F(ab')<sub>2</sub> probe and a second whole-body scan was done ~21 hours after probe  
127 injection with the PET/CT guided necropsy done immediately after. For the third animal (JF82),  
128 the 1<sup>st</sup> PET/CT scan at week 1 post infection was performed ~22 hours after IV probe

129 administration. On day 13, this same animal, JF82, was evaluated at week 2 post-infection by  
130 whole-body scan 18 hours after probe administration followed by necropsy and subsequent  
131 scans.

132

### 133 **SARS-CoV-2 infection characteristics**

134 SARS-CoV-2 infection of the 3 animals was monitored via classical hematoxylin and eosin  
135 (H&E) staining for evaluation of lesions in lung tissue (Fig 1C-E) and via quantification of  
136 genomic and subgenomic RNA in nasal swabs and saliva (Fig 1F, G). Pathology varied from  
137 minimal in LP14 (Fig 1C), to mild in IN22 (Fig 1D) and JF82 (Fig 1E). These findings are consistent  
138 with the pulmonary pathology of SARS-CoV-2 infected rhesus macaques observed in other  
139 studies performed at the Tulane National Primate Research Center<sup>17, 25</sup>. The pulmonary  
140 pathology consisted of variable interstitial inflammation and type II pneumocyte hyperplasia  
141 (IN22 and JF82), which in the most severely affected animal (IN22) also exhibited prominent  
142 atypia. Fig 1F and G shows the level of genomic (Fig 1F) and subgenomic (Fig 1G) RNA in nasal  
143 swabs and saliva for all 3 animals. No obvious differences were noted in viral loads between the  
144 3 animals.

145

### 146 **Distribution of SARS-CoV-2 signal after 1 week of infection with the WA1 isolate**

147 The three PET/CT scans of LP14, including the whole body (Fig 2A and B, S1-video), the organ  
148 scan (Fig 2C, D, and E, S2-video) and the tissue scan (Fig 2F), revealed probe signal at a number  
149 of distinct anatomical sites. As expected, there was a strong signal in the kidneys, which is a  
150 consequence of the excretion of the radiolabeled probe. To better evaluate the probe signal in

151 the lungs, the 3D reconstruction of the lungs was isolated from the PET datasets, and the lung  
152 signal was projected over the CT reconstruction of the skeleton (Fig 2G and H, S3-video). The  
153 signal associated with the lungs was diffuse and quite uniform throughout the tissue as  
154 observed in the whole animal scan. This is more evident in the projection of the lung signal  
155 without CT (Fig 2I and J, S3-video). However, the lung signal was more evident in the post  
156 necropsy organ scan when the intact respiratory tract including the tongue were scanned again  
157 (Fig 2C). In this case, lungs were no longer inflated within the body increasing signal density,  
158 leading to higher signal in the 2<sup>nd</sup> scan. Two different respiratory tract z-series images (Fig 2K  
159 and L) reveal a focus of signal associated with the base of the tongue, overlapping with the  
160 pharynx as evidenced by the cartilaginous structures seen in the CT. There were abundant small  
161 foci of signal distributed throughout the lung tissue, often adjacent to the trachea and bronchi  
162 as they branch out into the lungs. In addition, the z-series' reveal that the observed PET signal is  
163 associated with the tissues and not with the open airways of the bronchus and ever narrowing  
164 bronchi. Immunofluorescence microscopy revealed areas of infected cells lining alveoli in lung  
165 tissue sections that had PET/CT signal (Fig 2M and N) confirming the specificity of the PET  
166 signal.

167 In contrast to the weak, diffuse signal associated with the lungs, there was a strong and  
168 more focal PET signal within the MGT as shown in the front (Fig 3A) and side (Fig 3B-C) views  
169 (S4-video). The testes have a generally diffuse signal with some concentration of signal at the  
170 dorsal and ventral surface of both LP14 testes. The MGT of the rhesus macaque is similar to  
171 that of humans but is distinct in several ways. Most notably, it is primarily retracted within the  
172 body covered by a prepuce with a small bone located within the glans penis known as the

173 baculum (visible in the CT scan of the animals, Fig 3B and C, red arrow). There was a very  
174 pronounced PET signal associated with the root of the penile tissues, which is buried within the  
175 abdomen. The 3D PET signal was projected in green in a front (Fig 3D) and side view (Fig 3E) to  
176 better illustrate the signal associated with the MGT and to visualize the signal from the root of  
177 the penis (see S5-video). The localization of the PET signal for the penis and testes in the  
178 context of the skeletal CT signal is shown in three different projections in panels 3F, 3H, and 3J,  
179 and isolated in panels 3G, 3I, and 3K (S6-video). The testis overlays shown in Fig 3L-O reveal  
180 that the PET signal is primarily associated with the testis and is distributed throughout the  
181 testicular tissue. There is also some potential signal associated with the epididymis.

182           In anticipation of a potential signal in the testes, which are known to express the SARS-  
183 CoV-2 receptor ACE2, we had designated the testes to be a component of the organ scan post  
184 necropsy. Unfortunately, much of the penis tissue was discarded at the necropsy of LP14,  
185 though we were able to isolate a small piece of penile tissue remaining within the abdomen.  
186 This small piece of penile tissue retained PET signal as can be seen in Fig 2 (Fig 2F: row 8 column  
187 5, Fig S2). To potentially identify infected cells within the testicular tissue of LP14, we evaluated  
188 tissue sections for expression of SARS-CoV-2 proteins and host proteins using  
189 immunofluorescence microscopy. In LP14, we found that ACE2 is expressed in the peritubular  
190 myoid and Sertoli cells surrounding/lining the base of the seminiferous tubules (Fig 4A). Next,  
191 we stained testicular tissue sections from LP14 with an anti-SARS-CoV-2 guinea pig serum.  
192 Infected cells were evident in seminiferous tubules but were not widely distributed and were  
193 instead localized in small clusters of cells at the base of the seminiferous tubules (Fig 4B).  
194 Infection of Leydig and other interstitial cells could not be evaluated due to loss of these cells

195 during tissue processing. To further investigate the phenotype of infected cells, we stained with  
196 markers to help identify peritubular myoid cells (smooth muscle actin) and Sertoli cells  
197 (vimentin). SARS-CoV-2 anti-serum colocalized with vimentin staining at the base of the tubules,  
198 indicating that Sertoli cells are being infected (Fig 4C). However, SARS-CoV-2 staining was  
199 sometimes observed in cells negative for vimentin indicating that cellular targets exist in  
200 addition to Sertoli cells (presumably germ cells because of their localization) (Fig 4C, arrow  
201 heads).

202

### 203 **Distribution of SARS-CoV-2 Delta variant signal after 1 week of infection**

204 Because of the mild disease manifestations of SARS-CoV-2 WA1 seen in many rhesus macaque  
205 studies, we utilized the Delta variant for the next set of animals, which had become the  
206 dominant circulating variant at the time of this study<sup>26</sup>. For IN22, at 1-week post infection, we  
207 performed 2 PET/CT scans at 3- and 21-hours post probe injection to gain insights into the  
208 dynamics of the probe distribution over time. This is an important aspect of probe function  
209 because as the probe distributes from circulation into the tissue it will encounter virally  
210 infected cells which will affect its distribution pattern. The three PET/CT scans of IN22, the  
211 whole body (Fig 5A-D and S7-video, S8-video), the organ scan (Fig 5E-H and S9-video) and the  
212 tissue scan (Fig 5I) are shown in Fig 5.

213 The front and side views of the 3-hour scan (Fig 5A, B and S7-video) and 21-hour scan  
214 (Fig 5C, D and S8-video) reveal a highly dynamic system of probe distribution demonstrating  
215 that the timing of the PET/CT scan after probe injection is an important consideration. The 3-  
216 hour scan clearly captures a robust probe signal in the vasculature and chambers of the heart,

217 consistent with a large fraction of the probe still circulating in the blood after IV injection. A  
218 strong lung signal is apparent in the 3-hour scan in contrast to the previous animal. Some signal  
219 was also observed in the MGT with a very strong signal observed in the prostate in the 3-hour  
220 scan. In the 21-hour scan, the lung probe signal remained much greater than observed in LP14  
221 and was further distributed throughout the tissue. The prostate signal remained but decreased  
222 substantially in the 21-hour scan while signal in the MGT was further amplified. For the most  
223 part, an increase in signal was seen at tissue sites of probe labeling in the 21-hour scan. In  
224 contrast, the vasculature signal decreased substantially, consistent with the movement of the  
225 probe from blood, into tissues. However, some discrete probe labeling of certain vascular sites  
226 remained, possibly indicating infection of the vasculature.

227 To better evaluate the probe signal in the lungs after Delta infection, the 3D  
228 reconstruction of the IN22 lungs was isolated from the PET datasets, and the lung signal was  
229 projected over the CT reconstruction of the skeleton (Fig 6A-D, S10-video). Both the 3-hour and  
230 21-hour signals are significant and localized. The lung rotation series (Fig 6E and F) reveal a  
231 major signal associated with the caudodorsal portion of the right lung and less signal associated  
232 with the left lung. Single z images of the PET and CT signal in sagittal and transverse sections is  
233 shown in Figs 6G-J to better facilitate the analysis of the relationship of CT revealed lung  
234 pathology with the PET signal. This comparison reveals an overlap of the opaque lung signal and  
235 greater PET signal in the right lung in contrast to the more CT transparent left lung tissue (Fig  
236 6G-J). The stronger PET signal in the right lung observed in the whole-body scan is recapitulated  
237 in the organ scan (Fig 6K-O). This animal had overt gross pathology associated with the dorsal  
238 aspects of the right lower lung lobe as highlighted in the magnified inset (Fig 6L).

239 Histopathology of this region revealed marked pulmonary interstitial inflammation and  
240 type II pneumocyte hyperplasia (Fig 1D, and 6P-S). The projection of the PET signal over the  
241 photo (6N) shows a strong PET signal in multiple lung lobes and located adjacent to the focally  
242 extensive areas of consolidation (red and inflamed areas). A similar strong PET signal is  
243 observed in several areas of the left lung, with a major PET signal associated with the caudal  
244 aspect of the upper lobe of the left lung. An overlay of the unnormalized PET over a CT  
245 projection that reveals lung structure and fluid in the lung (Fig 6O) further details the  
246 relationship between the areas with evidence of pneumonia and the PET signal. The PET signals  
247 tend to be adjacent to opaque regions potentially caused by fluids and the regions of  
248 consolidation visible in the photo.

249 Next, we evaluated paraffin blocks of the right lower lobe by H&E (Fig 6P and R) and  
250 immunofluorescent staining for SARS-CoV-2 (Fig 6Q and S). In regions of pneumonia (Fig 6P),  
251 the interstitium and alveolar spaces are expanded by inflammatory infiltrate. In these same  
252 regions, SARS-CoV-2 infected cells are scattered throughout (Fig 6Q). Higher magnification  
253 imaging of the H&E stain (Fig 6R) reveals the inflammatory infiltrate is composed predominately  
254 of macrophages with lesser neutrophils (arrowheads). Alveolar septa are frequently lined by  
255 type II pneumocytes (arrows). SARS-CoV-2 staining (Fig 6S) reveals infected cells within alveoli  
256 (arrows) and lining alveolar septa (arrowheads).

257 To validate the accuracy of our SARS-CoV-2 staining results, 2-color  
258 immunofluorescence staining for spike and nucleocapsid was used to identify SARS-CoV-2  
259 infected cells in the right lung (Fig 6T). Spectral imaging confirmed that the fluorescence signal  
260 associated with the double positive cells is consistent with the specific fluorophores utilized for

261 antigen visualization. Additional fluorescent staining shows focal nature of infected cells in a  
262 large piece of lung tissue (Fig 6U-W). The 2-color imaging is a powerful method to validate the  
263 identification of SARS-CoV-2 infected cells. Spectral imaging of left lung tissue stained for NC  
264 and dsRNA was used as an alternate approach to identify infected cells (Fig is shown in panels  
265 6X-Z). The spectrum shown in Fig 6Z confirms that the cells identified in panel 6Y are  
266 specifically double stained with the antibodies to dsRNA and SARS-CoVCoV-2 NC.

267 To evaluate the probe signal in the MGT after Delta infection, we compared the 3-hour  
268 and 21-hour PET/CT signal in the IN22 MGT (Fig 7A-D); the isolated PET signal of the MGT of  
269 both scans is shown below (Fig 7E-H). A signal is apparent in the base of the testes that  
270 becomes more diffuse at the 21-hour timepoint. There is also a signal apparent just above both  
271 testes in the 3-hour scan that increases at 21-hours and is most prominent above the right teste  
272 (Fig 7A-H, indicated by white asterisk). Examination of both scans indicates that the probe  
273 signal was initially associated with the vasculature, but it persisted and accumulated adjacent to  
274 the top of testes in the 21-hour scan. This PET signal is associated with the vasculature of the  
275 spermatic cord as is visible in the CT projections and the PET overlays in the 21-hour scan (Fig  
276 7I-L) and after the necropsy (Fig 7M-P). The post necropsy signal matches the *in vivo* scan with  
277 the left testicle having a persistent signal throughout the spermatic cord and a more localized  
278 signal on the top of the right teste. To confirm infection in these tissues, the tissue block with  
279 the greatest PET signal (L Test 1, Fig 5I) was sectioned for genomic and microscopic analysis.  
280 Bulk RNA was isolated from 2 tissue sections and qPCR analysis of the SARS-CoV-2 N gene  
281 revealed the presence of viral RNA (2.03 Copies N1/ul). Immunofluorescence analysis of the  
282 PCR positive tissue derived from the same block revealed the presence of sparse cells double

283 positive for spike and nucleocapsid primarily found in the interstitial space (Fig 7Q and R).  
284 Staining of penile tissue from an uninfected macaque (Fig 7S) reveals robust ACE2 expression in  
285 the venous spaces of the corpus cavernosum. Multiple SARS-CoV-2 infected cells in the penis  
286 were revealed by double staining for nucleocapsid and dsRNA (J2) (Fig 7T-W).

287

### 288 **Longitudinal analysis of SARS-CoV-2 Delta variant distribution 1- and 2-weeks post-infection**

289 For the final pilot study, we performed two longitudinal PET/CT scans, at 1- and 2-weeks post  
290 challenge with the Delta variant, on a single animal (JF82). The goal of this study was to  
291 determine if the  $^{64}\text{Cu-F(ab')}_2$  probe could provide novel insights into the spatiotemporal  
292 dynamics of SARS-CoV-2 infection with sequential PET/CT scans. A front and side view of the  
293 sequential PET/CT scans at 1-week (Fig 8A-B) and 2-weeks (Fig 8C-D) reveals dynamic changes  
294 in various organ systems. For example, there is a decrease in the signal of the lungs between  
295 week one and two while MGT signal increases. These changes are illustrated in the front (Fig  
296 8E) and side (Fig 8F) view overlay of the 1-week (shown in red) and 2-week (shown in blue)  
297 timepoints. Areas with blue signal indicate increased signal in week 2 relative to week 1 and  
298 areas with red signal indicate where the week 1 scan had greater signal. Areas with white signal  
299 indicate where there is high PET signal in both scans. The post necropsy organ scan (Fig 8G-J,  
300 S7-video) and the tissue scan (Fig 8K) similarly show probe signal associated with both the lungs  
301 and MGT.

302 To better compare the probe signal in the lungs of JF82 at the 1-week (Fig 9A-B) and 2-  
303 week (Fig 9C-D) timepoints, the 3D reconstruction of the JF82 lungs was isolated from the PET  
304 datasets and projected over the CT reconstruction of the skeleton (Fig 9A-D). Both the 1- and

305 2-week lung signals are apparent and localized with a level of signal comparable to the previous  
306 animal (IN22) infected with the Delta variant. An evaluation of the data set revealed a PET  
307 signal overlying a region of opacity in the lower lobe of the left lung as designated with the  
308 asterisks in several of the panels (Fig 9A-B, 9G-L). The lung rotation series shown for week 1  
309 (Fig 9E) and week 2 (Fig 9F) reveal a major signal associated with the dorsal side of the left lung  
310 at both timepoints and less signal associated with the right lung in the week 1 scan. Evaluation  
311 of signal from coronal sections of the week 1 PET/CT overlay (Fig 9G) and CT alone (Fig 9I)  
312 reveals an overlap of the probe signal with an opaque region consistent with focal pneumonia.  
313 It is notable that both the PET and CT signal associated with this spot in the left lung are gone in  
314 the week 2 scan (Fig 9H and J). This is consistent with reports that the lung pathology observed  
315 in the rhesus macaque model is most apparent after 1 week of infection and can wane by week  
316 2<sup>25</sup>. To better illustrate the change between week 1 and week 2, the week 1 scan in red and the  
317 week 2 scan in blue were overlaid with the week 1 CT signal (Fig 9K and L). Microscopic analysis  
318 revealed pulmonary infiltrates were still present in the alveolar space at necropsy (Fig 1E).  
319 However, no infected cells were detected with immunofluorescence using an anti-SARS-CoV-2  
320 antibody in FFPE tissue. These findings are suggestive of a resolving infection which is  
321 supported by the histopathology (Fig 1E) and viral RNA levels (Fig 1F and G).

322 We next evaluated the signal associated with the MGT of JF82 as illustrated in Fig 10,  
323 which presents the front and near side view (~45°) of the abdominal area of the week 1 (Fig 10A  
324 and D), week 2 (10B and E), and overlay (10C and F). The overlay (Fig 10C and F) reveals the  
325 dynamics of the probe signal in the MGT of JF82 in the first 2 weeks of SARS-CoV-2 infection.  
326 The white signal in the overlay reveals that the probe signal is maintained in the prostate, the

327 vasculature at the base of the spermatic cord, and the base of the testes. To gain additional  
328 insights into the MGT associated signal at the 2 time points, we isolated the MGT volumes and  
329 3D projected the signal (Fig 10G-J). In the week 1 scan (Fig 10G-H), a signal associated with the  
330 root of the penis is also apparent in addition to the signal associated with the vasculature at the  
331 base of the spermatic cord and the base of the testes. In the week 2 scan, the signal becomes  
332 more diffuse, spreading throughout the penis and testes, and extending into the spermatic  
333 cord, especially into the right spermatic cord. To better visualize the signals associated with the  
334 different tissues, we isolated the volumes containing the penile signal for the week 2 scan (Fig  
335 10K-M). The signal distribution throughout the penis at week 2 is readily apparent and distinct  
336 from the signal associated with the spermatic cord. It is notable that the probe signal associated  
337 with the MGT becomes better distributed and more pronounced in the week 2 scan, consistent  
338 with a spreading infection in the MGT between week 1 and week 2. In contrast, a focus of  
339 infection in the right lung (Fig 9) of the same animal is observed in the week 1 scan and  
340 resolved in the week 2 scan.

341         Histopathology of testicular tissue from JF82 revealed multifocal regions of degenerate  
342 seminiferous tubules characterized by a complete loss of germ cells and spermatids (Fig 10N).  
343 These regions also have evidence of edema as revealed by increased spaces between individual  
344 seminiferous tubules. Degenerate seminiferous tubules occasionally contained macrophages  
345 with phagocytosed spermatids, and the adjacent interstitium was infiltrated by low numbers of  
346 lymphocytes and plasma cells. To further characterize the degenerative changes noted on H&E,  
347 immunofluorescence for CD206 - a mannose receptor present on monocytes, macrophages<sup>27</sup>,  
348 and mature spermatids<sup>28-30</sup> - and caspase 3 - a cellular marker of apoptosis - was performed.

349 Degenerate seminiferous tubules were readily identified by the marked decrease in CD206  
350 expression (due to loss of mature spermatids) and increased expression of caspase 3 compared  
351 to adjacent, nondegenerate, tubules (Fig 10O, Q-S). Evidence of intra-tubule macrophages was  
352 readily apparent (Fig. 10R, S). SARS-CoV-2 infected cells can be identified in the JF82 testes with  
353 triple staining for NSP8, nucleocapsid, and SARS-CoV-2 anti-sera (Fig 10T and U).

354

### 355 **Comparison of PET signal between animals**

356 A comparison of the PET/CT scans of 3 SARS-CoV-2 infected rhesus macaques is revealing in  
357 terms of the dynamics of infection and the utility of this technique to study COVID-19. In Fig  
358 11A-D we present a comparative rotation series of the PET signal withing the lung volumes of  
359 all scans. Although there are differences in the lung signal of each scan, the Delta variant  
360 utilized for infection of IN22 (Fig 11B) and JF82 (Fig 11C-D) is associated with increased  
361 pathology<sup>26</sup> (Fig 1C-E, Fig 5, and Fig 8) and increased PET signal (Fig 11B-D) without a clear  
362 difference in viral load in nasal swab or saliva at 1 week after challenge (Fig 1F and G) compared  
363 to LP14. This is consistent to similar viral loads between WA1 and the Delta variant in a recent  
364 report<sup>26</sup>.

365 The probe signal associated with the MGT was not anticipated, but apparent in all 3  
366 animals. This reveals that infection of MGT is consistently seen in the rhesus macaque model of  
367 SARS-CoV2 IN/IT challenge. A comparison of the isolated MGT PET signal from the four whole-  
368 body PET scans of 3 SARS-CoV-2 infected rhesus macaques (Fig 11E-H) presented as a rotation  
369 series further reveals the dynamics of SARS-CoV-2 after infection. The difference in MGT signal  
370 between the animal infected with WA1 (LP14) and the animals infected with the Delta variant

371 (IN22 and JF82) at week 1 is much less pronounced than that seen in the lungs. In all week 1  
372 MGT scans, the signal is asymmetrically distributed with diffuse signal throughout the testicles,  
373 an increased signal at the base and top of the testes, and a signal associated with the root of  
374 the penis (Fig 11E-G). The MGT PET signal is visibly increased in the week 2 scan relative to the  
375 week one scan (Fig 11G, H) for JF82 indicating further spread of infection into the MGT at that  
376 time. Another obvious difference between the week 1 whole-body PET scans is a variable signal  
377 associated with the heart and liver as shown in Fig 11I-K. LP14 had a diffuse PET signal  
378 throughout the liver (Fig 11I). In contrast, the IN22 PET signal (Fig 11J) was primarily localized  
379 with the right side of the liver and in JF82 the PET signal (Fig 11K) was localized to the base of  
380 the liver. Additionally, the extent of labeling of the heart is variable with JF82 and IN22 having a  
381 greater signal than LP14 (Fig 11L).

382 To take advantage of the quantitative aspects of PET detection, we isolated the total  
383 standard uptake value (SUV) of the PET signal associated with the CT defined volumes as  
384 plotted in Fig 11L. The 3 animals scanned 1 week (W1) post SARS-CoV-2 challenge are  
385 presented together for the whole-body (WB) scan signal and all evaluated tissues. The single  
386 week 2 (W2) PET signal of JF82 is presented for comparison. The WB values for all scans are  
387 clustered revealing the reproducible nature of evaluation of the PET signal. An increase in the  
388 total SUV between week 1 and week 2 for the MGT and testes volumes is consistent with the  
389 increase of signal suggested by visual inspection of the isolated tissues (Fig 10, Fig 11G and H).

390 Another relevant tissue with PET signal observed in all 3 animals is the prostate. Probe  
391 labeling of the prostate first became apparent in the early PET scan (3 hr. after injection) of  
392 IN22 where it was among the strongest, non-kidney associated signals (Fig 5A and B).

393 Therefore, we reevaluated the PET/CT data sets for the 3 animals. We were able to detect a  
394 signal associated with the prostate in all animals (marked by white asterisks, Fig 12A-F). An  
395 inset showing a sagittal slice of the PET/CT shows the localization of the prostate within the  
396 small white circle for each animal. PET signal was also isolated within the penile volume of the  
397 whole-body scan for IN22 1-week post infection (Fig 12G-I) and 2-weeks post infection for JF82  
398 (Fig 12J-L). LP14 is excluded from this analysis because the penile tissue was not collected. The  
399 same general distribution of PET signal is seen in the organ scan of IN22 (Fig 12M) and JF82 (Fig  
400 12N). The localization of the PET signal is further defined in the tissue scan of the cryomolds  
401 shown with (Fig 12O and Q) and without (Fig 12P and R) PET signal for each animal. There is  
402 PET signal associated with the penile tissue with a stronger signal associated with the penile  
403 root of IN22 and the glans of JF82. This PET/CT guided necropsy of the MGT reveals a  
404 persistent signal associated with the penile tissue of these 2 animals. All 3 animals had an  
405 apparent PET signal associated with the testes at the 1-week timepoint and that signal  
406 increased in the testes in the week 2 scan (Fig 12Q-T, quantified in Fig 11O). The  
407 histopathologic analyses of the testes from all three animals are shown in Fig 12S-U. Testicular  
408 degeneration was noted in seminiferous tubules of JF82 (Fig. 10N). Panels demonstrate normal  
409 spermatogenesis or lack thereof in JF82 (Fig. 12N, O, R, S).

410 In addition, all animals had a PET signal located at the top of each testicle, where the  
411 spermatic cord connects with testicle. A dissection of the rhesus macaque testicular anatomy is  
412 shown in Fig 13A-C. The spermatic cord contains the vasculature supplying blood to the  
413 testicles, the vas deferens which transports mature sperm produced in the testes, and the  
414 cremaster muscle (Fig 13A). The position in natural context of the macaque penis, testes, and

415 spermatic cord are shown in Fig 13B. A magnified view of the vasculature of the pampiniform  
416 plexus is shown in Fig 13C. As shown in the IN22 MGT PET/CT series (Fig 13D-G), there is a  
417 major signal associated with the top of the testicles, especially the right testicle. A further  
418 examination of this signal within the PET/CT data set demonstrates it is located just above the  
419 testicle in the yellow volume (Fig 13D-G). This yellow volume is overlapping with a vasculature  
420 structure consistent with the pampiniform plexus visualized by CT (Fig 10G and B). The signal  
421 associated with the pampiniform plexus and spermatic cord is seen in the 1-week scan of all  
422 animals in front (Fig 13H, J, and L) and rotate 45° view (Fig 13I, K, and M) outside of the ovals  
423 indicating the testes. The signal associated with the pampiniform plexus and spermatic cord for  
424 LP14 can be seen outside of the white ovals (Fig 13L-Q).

425

#### 426 **Principal component analysis of PET SUV signals**

427 The PET signal includes several parameters in each anatomical area, each of which provide  
428 different insights into the distribution of the probe within the tissue. For example, the total SUV  
429 (Fig 11L), provides insights into the overall signal in each tissue/animal. However, the total SUV  
430 does not account for variability in tissue size and shape. The mean SUV provides insights into  
431 the relative intensity of PET signal in each tissue (Fig 14A). This comparison of mean SUV reveals  
432 the relative intensity of the signal across tissues, with the prostate having consistently high  
433 signal in all animals. In contrast, the total SUV/whole body Total SUV for the different tissues  
434 illustrates the percentages of the total whole-body signal in each tissue without consideration  
435 of the size of each tissue relative to the other (Fig 14B). All 7 PET parameters for each tissue are  
436 shown in the heatmap (Fig 14C), which reveals that different tissues have unique signal

437 characteristics. From this analysis, it is evident that the prostate signal of IN22 and JF82 have  
438 the highest mean SUV and standard deviation with relatively a high median SUV being also seen  
439 in the prostate of the 3<sup>rd</sup> animal LP14. For example, the prostate signal of IN22 and JF82 has the  
440 highest mean SUV and standard deviation with relatively a high median SUV being also seen in  
441 the prostate of the 3<sup>rd</sup> animal LP14, indicating a more clustered signal compared to the tissues  
442 with the highest total SUV.

443 To facilitate the use of our PET data to gain insights into our data set we utilized  
444 Principal Component Analysis (PCA) followed by hierarchical clustering to examine the data  
445 from all scans of the 3 animals. To cluster tissues according to their SUV signal characteristics,  
446 we applied PCA including all variables obtained from the SUV measurements (i.e., Total SUV,  
447 Total SUV Whole Body ratio, Mean SUV, Median SUV, Standard Deviation SUV, Max SUV, and  
448 Kurtosis) for each tissue and animal. After this analysis, we observed 4 different clusters that  
449 correspond to tissues that display very distinct SUV signals. The clustering captures the prostate  
450 signal described in the heat map where they are part of cluster 4 (dark blue group). Of note, the  
451 major right lung signal of IN22 also clusters within this group, while the prostate signal of LP14  
452 does not (Fig 14D). The evident PET signal observed in the lungs of the Delta variant animals  
453 IN22 and JF82 are part of the cluster 3 (green group) (Fig 14D) revealing their similarity with its  
454 small foci of high signal and increased kurtosis value (indicating data heavy tails or more  
455 outliers) consistent with the signal variability. The higher kurtosis is also associated with penile  
456 and testes signal of all the animals in the red and light blue clusters 1 and 2. This analysis allows  
457 us to begin to appreciate the nature of the PET signal associated with the different tissues,  
458 different animals, different viruses, and identify outliers.

459

460 **Discussion:**

461 The goal here was to develop a F(ab')<sub>2</sub> based immunoPET probe to allow the visualization of  
462 SARS-CoV-2 spike protein expression in the rhesus macaque infection model. This model is  
463 clinically relevant as it was used to develop the highly successful vaccines now available against  
464 SARS-CoV-2<sup>31, 32</sup>. The ability to detect anatomical sites of SARS-CoV-2 infection will facilitate  
465 our understanding of COVID-19 disease severity and the mechanism of comorbidities in the  
466 development of pathology. It could be especially useful in understanding long-COVID and its  
467 underlying causes<sup>33, 34</sup>. This pilot study is a key step in the clinical development of this PET  
468 probe to visualize SARS-CoV-2 replication and to facilitate treatments for COVID-19. The  
469 distribution of the probe is complex, but it can reveal sites of SARS-CoV-2 infection in the rhesus  
470 macaque model.

471 The utility of the probe is best demonstrated by the temporal association of the PET  
472 probe with CT detected lung pathology between weeks 1 and 2 in JF82. A PET signal was clearly  
473 associated with an opaque region (pneumonia) in the left lung in the week 1 scan, but both the  
474 PET signal and CT detected pneumonia are not present in the week 2 scan, validating this  
475 technique. The overlays, shown in Fig 9, further illustrate this transient lung pathology  
476 detected by comparing the two PET/CT scans separated by one week. Supporting this  
477 interpretation of the PET/CT data, the pathology report shows that the left lung of JF82 has  
478 type II pneumocyte hyperplasia and inflammatory infiltrate consistent with the normal course  
479 of infection observed in the rhesus macaque model. Overall, the lung pathology associated  
480 with SARS-CoV-2 in our three animals was consistent with the observation of many infected

481 rhesus macaques where the lung pathology was typically mild and peaked at 1 week after IN/IT  
482 challenge. This dynamic was generally observed for lung associated signal in this limited pilot  
483 study. There was some consolidation and inflammation observed in animal IN22 and this  
484 coincided with an adjacent PET signal in both animals infected with the Delta variant.

485 Further validation of the PET/CT probe's ability to identify areas of infection at sites  
486 other than the lungs and its utility in understanding COVID-19 pathogenesis was the revelation  
487 of a reproducible infection of the MGT. In all three animals, the probe was associated with the  
488 prostate, penis, pampiniform plexus, and testicles. We have been able to identify SARS-CoV-2  
489 infected cells in the testicles of all 3 animals. Comparing the longitudinal PET scans of JF82  
490 reveals that while the lung pathology and signal wane between week 1 and 2, the signal of the  
491 MGT, and more specifically in the testicles increases in week 2. Consistent with increased  
492 testicular infection at week 2 indicated in the PET scan, H&E staining of the JF82 testes revealed  
493 a unique pathology consisting of denuded stretches of the twisted and intertwined  
494 seminiferous tubules (presenting as a tube cluster). Spermatids were absent in these  
495 degenerate regions and the remaining Sertoli cells were undergoing apoptosis, seen through  
496 caspase 3 staining (Fig. 10S). Local inflammation, or orchitis, was suggested by immune  
497 infiltrates (Fig. 10R). Both the PET signal and pathology is greater in the left testicle of JF82.  
498 Staining macrophages and mature spermatids for CD206 and all cells for caspase 3 activation  
499 reveals a severe, acute response within short stretches of the seminiferous tubules where the  
500 Sertoli cells are undergoing apoptosis due to inflammasome activation (caspase 3 activation),  
501 and no spermatids are present consistent with an ongoing acute infection (Fig. 10N-S). We  
502 have detected infected cells within the JF82 testes ((Fig. 10T, U) and the relationship between

503 the infected cells and testicular pathology is ongoing. Similar decreases in the cellular content  
504 of the seminiferous tubules and sloughing of Sertoli cells and spermatids into the lumen have  
505 been reported in multiple studies of autopsy tissues from COVID-19 related fatalities<sup>35-40</sup>.

506 Our results suggest that SARS-CoV-2 rapidly and efficiently infects multiple tissues of the  
507 male genital tract (MGT) early during infection in rhesus macaques. The complex vasculature  
508 and known ACE2 expression of the tissues of the MGT make it a potential target of the virus<sup>11</sup>,  
509 <sup>41-43</sup>. The SARS-CoV-2 infection of the testicles has been reported in mouse and hamster  
510 respiratory challenge models<sup>44-46</sup>. Likewise, the testicles are also a target of Ebola and Zika virus  
511 during systemic infection<sup>47</sup>. We observed a similar distribution of PET-probe signal in all 3  
512 animals in the week 1 scan with labeling of the prostate, root of the penis, the top the testicles  
513 and a second region of labeling at the base of the testicles (Fig. 11E-H). The signal above the  
514 testicles localizes to the pampiniform plexus and vasculature of the spermatic cord while the  
515 signal at the base of the testes is less clear, but appears to be associated with the cauda  
516 epididymis, the highly vascularized tail of the epididymis that serves as the storage site for  
517 mature sperm. A further dissection of the testicles before the organ scan should facilitate a  
518 detailed localization of the PET signal associated with the MGT in future studies.

519 Although these studies were done with a rhesus macaque model, it is reasonable to  
520 suggest that these observations may also apply to humans infected with SARS-CoV-2 because of  
521 several clinical observations relating to male sexual health and fertility. It is highly relevant in  
522 this extrapolation to consider that we have identified 4 distinct tissues where SARS-CoV-2  
523 infection could impact male sexual health and fertility: SARS-CoV-2 infection of the prostate,  
524 penis, pampiniform plexus, and testicles. The infection of the MGT and associated pathology

525 has been suggested by several publications and clinical studies. The prostate is known to be  
526 ACE2 positive.<sup>48</sup> Interest in SARS-CoV-2 infection of the prostate has focused on two areas. First  
527 is the potential impact on treatment of benign prostate hyperplasia<sup>49</sup> and prostate cancer<sup>50</sup>  
528 with androgen deprivation therapy on the severity of COVID-19<sup>51</sup> and secondly, the potential  
529 impact of SARS-CoV-2 infection on prostate cancer treatments. It is notable that prostate  
530 cancers are known to express high levels of transmembrane serine protease 2, TMPRSS2<sup>52</sup>,  
531 which is known to activate the SARS-CoV-2 spike protein to its optimal fusogenic potential<sup>53</sup>.  
532 Multiple studies have explored this space and it does not appear that SARS-CoV-2 infection is  
533 associated with an increase in prostate cancer<sup>54</sup>. In contrast, another study suggests that  
534 infection with SARS-CoV-2 may be associated with an increase in prostate specific antigen (PSA)  
535 detection in plasma<sup>55</sup>. Future studies are needed to confirm whether the robust signal of the  
536 SARS-CoV-2 PET/CT probe reflects a high-level infection of the human prostate and its  
537 subsequent impact on male sexual health and fertility<sup>56, 57</sup>. SARS-CoV-2 infection of the penis is  
538 potentially associated with the vasculature of the corpus cavernosum, which expresses high  
539 levels of ACE2 in the rhesus macaque and human penile tissue (Fig 7S)<sup>43, 58</sup>. Because the corpus  
540 cavernosum plays a key role in erectile function, the inflammation caused by SARS-CoV-2  
541 infection of the penile vasculature is hypothesized to lead to erectile dysfunction (ED). This has  
542 indeed been reported to be linked to COVID-19<sup>43, 59, 60</sup>. In addition, treatments for ED such as  
543 Viagra and Cialis are known to affect the renin-angiotensin-aldosterone-system where ACE2  
544 functions as a part of the physiologic regulation of blood flow associated with normal erectile  
545 function<sup>61</sup>.

546 A potential impact of COVID-19 infection on the pampiniform plexus might be suggested  
547 by several case reports of COVID-19 associated thrombosis located in the pampiniform plexus<sup>62-</sup>  
548 <sup>65</sup>. Additionally, the signal distribution of the left and right testes is distinct, with the signal of  
549 the right testicle being more focused at the top of the testicle while the signal on the left  
550 testicle being more distributed in the spermatic cord. This is reminiscent of the condition  
551 known as varicocele, which manifests as varicose veins of the scrotum, and is prominent in the  
552 left testicle relative to the right testicle<sup>66</sup>. This is due to the left testicle receiving its blood flow  
553 from the left renal vein which exposes it to higher blood pressure and slower blood flow<sup>67</sup>. This  
554 difference could be insightful if it is confirmed in more animals.

555 The potential infection of the testicles by SARS-CoV-2 could be highly impactful on male  
556 fertility, potentially decreasing sperm count and semen quality<sup>47, 68-70</sup>. It is known that SARS-  
557 CoV-2 infection in humans is associated with oligo- and azoospermia and a transient decrease  
558 in fertility after infection<sup>36, 38, 66, 68, 71, 72</sup>. One study found that fertility amongst infected men  
559 was reduced and returned to baseline 3-6 months after SARS-CoV-2 infection<sup>73</sup>. This decrease in  
560 fertility was not seen in infected women or men who received a SARS-CoV-2 vaccination. We  
561 find that the pathology associated with the testicles in the week 2 necropsy is extreme, with  
562 apparent ablation of sperm production within short regions of the seminiferous tubules and  
563 with accompanying immune infiltration consistent with an emerging COVID-19 associated  
564 orchitis<sup>64, 74</sup>. Multiple studies have reported a decrease in testosterone after SARS-CoV-2  
565 infection<sup>56, 75, 76</sup>. Leydig cells, which produce testosterone, are known targets of SARS-CoV-2<sup>35,</sup>  
566 <sup>37, 77</sup>. The decrease in testosterone correlates with disease severity<sup>76, 78</sup>. This susceptibility of  
567 the MGT to infection with SARS-CoV-2 may be consideration in the of higher mortality

568 associated with COVID-19 in men compared to women. The direct infection of the testicles  
569 observed in the NHP studies presented here are consistent with the MGT pathology reported in  
570 men<sup>35-40</sup>. The infection of the MGT may be a common outcome in SARS-CoV-2 infection. We  
571 suggest further study in mild, and even in asymptomatic infection, in men and macaques is  
572 clearly required. Because of the four distinct mechanisms negatively impacting human male  
573 sexual health and fertility, and the observation of all four mechanisms in all animals evaluated  
574 to date, we feel compelled to report this information at this early stage of study and evaluation.

575         Using a novel <sup>64</sup>Cu-labelled F(ab')<sub>2</sub> probe targeting the SARS-CoV-2 spike protein, we  
576 have found that it is possible to identify sites of SARS-CoV-2 infection in the rhesus macaque  
577 infection model using a PET/CT scan. The rapid and consistent spread of SARS-CoV-2 infection  
578 to the MGT in the first week of infection in the rhesus macaque suggests this could be an  
579 important post pandemic health consideration as those infected during the pandemic develop  
580 advanced disease and other manifestations of long COVID-19. Currently, there is no other  
581 methods that allows for the unbiased discovery of novel anatomical sites of SARS-CoV-2  
582 infection. We believe the immunoPET technique described here will be an important addition  
583 to the toolkit for studying and understanding SARS-CoV-2 pathogenesis. The availability of an  
584 immunoPET probe to SARS-CoV-2 in the clinical setting has the potential to reveal the  
585 underlying role of disseminated viral infection in long COVID and could guide therapeutic  
586 interventions to resolve SARS-CoV-2 related sequelae which could be a major health concern  
587 for the lifetimes of those infected during the COVID-19 pandemic.

588

589 **ACKNOWLEDGEMENTS:** This work was supported by a NOSI supplement (R37AI094595-10S1 PI:  
590 Hope) to parent grant R37AI094595 (PI Hope) and by NIH grants R21AI163912 (PI Hultquist)  
591 P51OD01110459, and U19AI135964 (E.A.O.). We would like to thank Nicholas Maness for  
592 supplying the delta variant virus and Maury Duplantis, Brooke F. Gasperge, Kasi E. Russell-  
593 Lodrigue, and the Veterinary team at TNPRC. Thanks to Rich D'Aquila for critical reading and  
594 editing of the manuscript.

595

596

## 597 **Material and Methods**

### 598 **Preparation of F(ab)<sub>2</sub>**

599 CR3022-IgG1 was acquired from Absolute Antibody (#Ab01680-10.0, Absolute Antibody). The  
600 IgG1 was digested into F(ab)<sub>2</sub> as previously described. Briefly, a Genovis FragIT antibody  
601 digestion kit (#A2-FR2-100, Genovis) was used according to manufacturer's protocol. CR3022  
602 was digested by adding to the FragIT column and rocking for 1 hr. at room temperature. The  
603 column was then centrifuged to elute fragments. Fc fragments were removed after incubation  
604 with the CaptureSelect Fc Column. F(ab')<sub>2</sub> fragments were eluted from this column and size  
605 was confirmed using SDS-PAGE.

606

### 607 **DOTA Labeling of Antibody**

608 CR3022-F(ab)<sub>2</sub> was labeled with the chelator dodecane tetra-acetic acid (DOTA) for the  
609 attachment of <sup>64</sup>Cu. Chelex 100 chelating resin (#142-1253, BioRad) was used to prepare two  
610 buffers: 0.1M sodium phosphate (pH 7.3) and 0.1M ammonium acetate (pH 5.5). Five grams of

611 Chelex was added to 100ml of each buffer and stirred at room temperature for 1 hour. Buffers  
612 were then filter sterilized using 0.22  $\mu$ M filters. CR3022-F(ab')<sub>2</sub> was buffer exchanged into the  
613 prepared 0.1 M sodium phosphate using Zeba columns (ThermoFisher, USA). DOTA-NHS-ester  
614 (#B-280, Macrocyclics) was dissolved in dimethyl sulfoxide (DMSO) at a concentration of 10mM.  
615 A 1:10 dilution of 1M sodium bicarbonate was made into a tube containing F(ab')<sub>2</sub> in sodium  
616 phosphate and 10mM DOTA was added at a molar ratio of 5:1. The tube was mixed and left to  
617 rock at 37C for 1.5 hours. The labeled F(ab')<sub>2</sub> was then buffer exchanged into fresh 0.1 M  
618 sodium phosphate using a Zeba column.

619

#### 620 **<sup>64</sup>Cu labeling**

621 Before labeling DOTA conjugated F(ab')<sub>2</sub> was buffer exchanged into freshly prepared 0.1M  
622 ammonium acetate (pH 5.5) prepared with Chelex 100 using 10kDa cutoff Amicon centrifugal  
623 microfilters (Cork, IRL). Cu<sup>64</sup> chloride was obtained from Washington University, St. Louis MO  
624 and shipped overnight to TNPRC. All work with Cu<sup>64</sup> was performed inside a lead castle. The  
625 radioactivity of the Cu<sup>64</sup> was measured using an Atom Force 500 dose calibrator and recorded.  
626 Next the Cu<sup>64</sup> was added to a tube containing the DOTA labeled F(ab')<sub>2</sub> in 0.1 M ammonium  
627 acetate and incubated at 37°C for 1 hour while rotating. The labeled F(ab')<sub>2</sub> probe was then  
628 separated from unlabeled Cu<sup>64</sup> and buffer exchanged into PBS via sequential centrifugation  
629 steps using 10kDa cutoff Amicon centrifugal microfilters to a final volume of ~20 $\mu$ l. The  
630 conjugated probe was then diluted to the final volume in PBS in sterile glass vials and drawn  
631 into single dose syringes. Each dose typically labelled in the 1-3 mCi per dose.

632

633 **Animals and virus**

634 The virus used for experimental infection of LP14 was SARS-CoV-2; 2019-nCoV/USA-WA1/2020  
635 (<https://www.ncbi.nlm.nih.gov/nuccore>; accession number MN985325.1) obtained from BEI  
636 resources (BEI #NR-52281). Virus stock was prepared in Vero E6 cells and sequence confirmed  
637 by deep sequencing. Plaque assays were performed in Vero E6 cells. Vero E6 cells were  
638 acquired from ATCC (Manassas, VA). The virus used for experimental infection of IN22 and JF82  
639 was SARS-CoV-2; hCoV-19/USA/MD-HP05647/2021 (Lineage B.1.617.2; Delta variant) obtained  
640 from BEI resources (BEI #NR-55672). Delta variant stock was expanded using Calu-3 cells and  
641 prepared as above using Vero E6 cells.

642 Three male rhesus macaques (*Macaca mulatta*) were used in this study. All animals were  
643 housed at the Tulane National Primate Research Center (TNPRC, Covington, LA) which is  
644 accredited by the Association for the Assessment and Accreditation of Laboratory Animal Care.  
645 All procedures were reviewed and approved by the Tulane University Institutional Animal Use  
646 Committee under protocol number P0452. One animal was inoculated with  $1.1 \times 10^6$  tissue  
647 culture infectious dose (TCID<sub>50</sub>) of the WA1 strain of SARS-CoV-2 via concomitant  
648 intratracheal/intranasal instillation (1mL intratracheal, 500 $\mu$ L per each nare). This animal was  
649 necropsied 8 days post-infection. The remaining two animals were inoculated with  $1.12 \times 10^6$   
650 TCID<sub>50</sub> of the delta variant of SARS-CoV-2 via the same route. One animal was necropsied at day  
651 7 and one at day 14 post-infection. All animals were intravenously infused with 0.5 mg/kg of  
652 the radiolabeled F(ab')<sub>2</sub> probe and JF82 was infused on two separate occasions. Macaque LP14  
653 received 4 mCi, JF82 and IN22 received 1.3 and 1.4 mCi respectively on Dec 9, and JF82 received  
654 an additional dose of 0.7 mCi on Dec 15. LP14 had nasal and salivary swabs taken at day 7. IN22

655 had swabs taken at days 3, 5, and 7 post-infection, while JF82 had swabs taken at days 3, 5, 7,  
656 and 14.

657

### 658 **PET/CT Imaging and Necropsy**

659 PET/CT guided necropsies were performed in three sequential phases each separated by a  
660 PET/CT followed by a period of analysis and sampling (1. whole-body, 2. organ, and 3. tissue).  
661 First, whole-body scans were acquired prior to sending the animal to necropsy. Following  
662 euthanasia, all major organ systems were removed (pluck, gastrointestinal tract, liver, spleen,  
663 kidneys, urinary bladder, testicles, penis, prostate, seminal vesicles, nasal turbinate, lymph  
664 nodes, carotid artery, cervical spinal cord, and brain) placed in a clear, plastic, sealable  
665 container and sent back to PET/CT for an “organ scan”. After the organ scans were  
666 reconstructed, “hot” regions of each major organ (as seen on the organ scan) were sampled  
667 and placed in cryomolds. The final “tissue” scan was acquired by placing the cryomolds in a  
668 clear, plastic, sealable container and scanning them with the PET/CT. Following acquisition of  
669 the tissue scan, cryomolds were filled with OCT and frozen on dry ice. All remaining tissue (not  
670 placed in cryomolds) was placed in zinc-formalin fixative. All samples were stored for 5 days  
671 before being removed from containment.

672

### 673 **PET/CT Image Analysis**

674 Acquired PET/CT whole-body images were analyzed using the MIM Software (MIM Software  
675 Inc., Cleveland, OH). The PET and CT scans were reconstructed using the software and PETCT  
676 fusions were created to analyze regions of interest through axial, sagittal, and coronal views.

677 The PET scans were presented in calculated Standardized Uptake Values, and all images were  
678 set to the same scale (0-20 SUVbw). The PET scale was selected based on the overall signal  
679 intensity of the PET scans, and the CT scale for optimal visibility of the tissues. Regions of  
680 interest (ROI) were isolated using a combination of the Region Grow function and manual  
681 contouring on a representative scan, then these regions were copied on subsequent scans of  
682 the same animal using a specialized developed workflow. This workflow allows the software to  
683 use the CT scans to map the selected ROI and locate that exact volume in subsequent scans.  
684 Manual adjustments were then used to counter any changes in the animals' orientation  
685 between scans. The areas within these regions were then extracted from the full scans, and the  
686 anatomical regions were analyzed in both 2D cross-sections and 3D projections. 3D views are  
687 maximum intensity projections of isolated ROI in the PET scans.

688 To cluster tissues according to their SUV signal characteristics, we used Principal Component  
689 Analysis (PCA) where we included all variables obtained from the SUV measurements (i.e., Total  
690 SUV, Total SUV Whole Body ratio, Mean SUV, Median SUV, Standard Deviation SUV, Max SUV,  
691 and Kurtosis) for each tissue and animal. The clustering of each tissue was subsequently  
692 obtained by agglomerative hierarchical clustering on the PCA results. After building an initial  
693 hierarchical tree, the sum of within-cluster inertia was calculated for each partition. The  
694 selected partition was the one with the higher relative loss of inertia. Both PCA and  
695 agglomerative hierarchical clustering were performed using FactoMineR package and  
696 Factoextra was used for visualization of the clustering results.

697

698 **Isolation and Quantification of viral RNA**

699 Viral load was quantified from pharyngeal and nasal swabs taken from infected animals at  
700 TNPRC as previously described (1) Swab and bronchial brush samples were collected in 200  $\mu$ L  
701 of DNA/RNA Shield 1 $\times$  (catalog number R1200; Zymo Research, Irvine, CA) and extracted for  
702 viral RNA using the Quick-RNA viral kit (catalog number R1034/5; Zymo Research). The Viral  
703 RNA Buffer was dispensed directly to the swab in the DNA/RNA Shield. A modification to the  
704 manufacturers' protocol was made to insert the swab directly into the spin column to  
705 centrifugate, allowing all the solution to cross the spin column membrane. The viral RNA was  
706 then eluted (45  $\mu$ L) from which 5  $\mu$ L was added in a 0.1-mL fast 96-well optical microtiter plate  
707 format (catalog number 4346906; Thermo Fisher Scientific, Waltham, MA) for a 20- $\mu$ L real-time  
708 quantitative RT-PCR (RT-qPCR) reaction. The RT-qPCR reaction used TaqPath 1-Step Multiplex  
709 Master Mix (catalog number A28527; Thermo Fisher Scientific) along with the 2019-nCoV RUO  
710 Kit (catalog number 10006713; IDTDNA, Coralville, IA), a premix of forward and reverse primers  
711 and a FAM-labeled probe targeting the N1 amplicon of the N gene of SARS2-nCoV19  
712 (<https://www.ncbi.nlm.nih.gov/nuccore>; accession number MN908947). The reaction master  
713 mix was added using an X-stream repeating pipette (Eppendorf, Hauppauge, NY) to the  
714 microtiter plates, which were covered with optical film (catalog number 4311971; Thermo  
715 Fisher Scientific), vortexed, and pulse centrifuged. The RT-qPCR reaction was subjected to RT-  
716 qPCR at a program of uracil-DNA glycosylase incubation at 25°C for 2 minutes, room  
717 temperature incubation at 50°C for 15 minutes, and an enzyme activation at 95°C for 2 minutes  
718 followed by 40 cycles of a denaturing step at 95°C for 3 seconds and annealing at 60°C for 30  
719 seconds. Fluorescence signals were detected with a QuantStudio 6 Sequence Detector (Applied  
720 Biosystems, Foster City, CA). Data were captured and analyzed with Sequence Detector

721 Software version 1.3 (Applied Biosystems). Viral copy numbers were calculated by plotting Cq  
722 values obtained from unknown (i.e., test) samples against a standard curve that represented  
723 known viral copy numbers. The limit of detection of the viral RNA assay was 10 copies per  
724 reaction volume. A 2019-nCoV–positive control (catalog number 10006625; IDTDNA) was  
725 analyzed in parallel with every set of test samples to verify that the RT-qPCR master mix and  
726 reagents were prepared correctly to produce amplification of the target nucleic acid. A non-  
727 template control was included in the qPCR to ensure that there was no cross-contamination  
728 between reactions.

729       OCT embedded tissue blocks were sectioned between 10-15  $\mu$ M and 2-4 sections were  
730 placed into RNase free tubes. RNA extraction was carried out using a RNeasy Plus Mini Kit  
731 (#74124, Qiagen), according to manufacturer’s protocol. Briefly, 350ul of lysis buffer with  
732 dithiothreitol (DTT) was added to the tubes containing sections. The tubes were vortexed  
733 briefly then frozen at -20C. Once thawed the samples were again vigorously vortexed then  
734 centrifuged for 3 minutes. Supernatant was removed and applied to the gDNA Eliminator spin  
735 column. The flow-through was mixed with 350ul of 70% ethanol and added to a RNeasy spin  
736 column. The spin column was washed three times with buffers RW1 and RPE. RNA was then  
737 eluted using 30-50ul of RNase free water. All steps prior to addition of lysis buffer were carried  
738 out in a BSL3 facility.

739

#### 740 **Tissue Processing and H&E Staining**

741 Tissue samples were collected in Zinc formalin (Anatech) and fixed for a minimum of 72 hours  
742 before being washed and dehydrated using a Thermo Excelsior AS processor. Upon removal

743 from the processor, tissues were transferred to a Thermo Shandon Histocentre 3 embedding  
744 station where they were submersed in warm paraffin and allowed to cool into blocks. From  
745 these blocks, 5um sections were cut and mounted on charged glass slides, baked overnight at  
746 60°C, and passed through Xylene, graded ethanol, and double distilled water to remove paraffin  
747 and rehydrate tissue sections. A Leica Autostainer XL was used to complete the  
748 deparaffinization, rehydration and routine hematoxylin and eosin stain. Slides were digitally  
749 imaged with a NanoZoomer S360 (Hamamatsu) and subsequently examined by a board-  
750 certified, veterinary pathologist using HALO software (Indica Labs).

751

#### 752 **Fluorescent Immunohistochemistry of FFPE tissues**

753 5um sections of Formalin-fixed, paraffin-embedded (FFPE) tissues were mounted on charged  
754 glass slides, baked for two hours at 60°C, and passed through Xylene, graded ethanol, and  
755 double distilled water to remove paraffin and rehydrate tissue sections. A microwave was used  
756 for heat induced epitope retrieval. Slides were heated in a high pH solution (Vector Labs H-  
757 3301), rinsed in hot water, and transferred to a heated low pH solution (Vector Labs H-3300)  
758 where they were allowed to cool to room temperature. Sections were washed in a solution of  
759 phosphate-buffered saline and fish gelatin (PBS-FSG) and transferred to a humidified chamber,  
760 for staining at room temperature. Lung sections were blocked with 10% normal goat serum  
761 (NGS) for 40 minutes, followed by a 60-minute incubation with the anti-SARS primary antibody  
762 diluted in NGS. Slides were washed and transferred back to the humidified chamber for a 40-  
763 minute incubation with the secondary antibody, also diluted in NGS. Sequential staining of FFPE  
764 testes, for CD206 and Caspase 3, was done as described above with 1% normal donkey serum

765 (NDS) being used in place of NGS for blocking and antibody dilutions. DAPI was used to label the  
766 nuclei of each section. Slides were mounted using a homemade anti-quenching mounting  
767 media containing Mowiol (Calbiochem #475904) and DABCO (Sigma #D2522) and imaged at  
768 20X with a Zeiss Axio Slide Scanner.  
769

770

#### 771 **Fluorescence Microscopy of OCT embedded tissues**

772 OCT embedded tissue were cryosectioned in a BSL3 facility between 10 and 15  $\mu$ M. One or two  
773 sections of each tissue were placed on glass microscope slides. Tissues were placed into an  
774 airtight container containing 4% PFA in PIPES buffer. The container was sealed and thoroughly  
775 decontaminated before being removed from the BSL3 facility. The remainder of the staining  
776 took place outside of the BSL3. Tissue sections were treated with L-lysine (0.1%, SigmaAldrich)  
777 to reduce background and non-specific interactions before being blocked using 3% BSA  
778 (Invitrogen, ThermoFisher) for 30 minutes at room temperature. Staining with primary  
779 antibodies was carried out at 37°C and secondary antibodies at room temperature. each for  
780 1hr. Table of primary and secondary antibodies used is below. All slides were stained with

781 Hoechst (1:25,000, ThermoFisher, USA) for 15 minutes and washed with PBS between all steps.  
782 Dako fluorescent mounting medium (#S302380-2, Agilent, USA) was used to mount cover slips  
783 which were sealed with nail polish. A DeltaVision Ultra inverted microscope (Cytivia, USA) was  
784 used to obtain images using the 10x, 20x, 60x, and 100x lenses. Images were deconvolved,  
785 stitched, and projected using the softWoRx software (Applied Precision, USA).

789 **Figure 1.** Study design and viral analysis of infected macaques. (A) Workflow of PET/CT guided  
790 necropsy. (B) Schematic showing the study design of probe administration, PET/CT scans, and  
791 infection. (C-E) Lung lesions were consistent with prior findings in NHPs infected with SARS-  
792 CoV-2 and varied from minimal in LP14 (C), moderate in IN22 (D), and mild in JF82 (E). Insets  
793 demonstrate the inflammatory infiltrate and in IN22 and JF82, type II pneumocyte hyperplasia  
794 (arrows). (F and G) Viral load measurements for all three animals. (F) shows copies/swab of  
795 genomic N while (G) shows copies/swab of subgenomic N.

796

797 **Figure 2.** LP14 PET/CT guided necropsy. (A and B) Whole-body PET/CT scans of LP14 8 days  
798 post-infection. Front view (A) and rotated 45° (B) both shown. PET signal is display as SUV. (C)  
799 Post necropsy PET/CT organ scan of LP14. (D and E) Images of tissues scanned in (C). (F) Overlay  
800 of PET signal onto photograph of small pieces of tissue in cassettes. (G and H) Lung PET signal  
801 was isolated and overlaid on whole body CT scans. Side (G) and front (H) view. (I and J) Isolated  
802 lung PET volumes used in G and H are shown independently, side view (I) and front view (J). (K  
803 and L) Single axial z-slice images of respiratory tract PET/CT signals are shown, each image  
804 represents a single z-plane from scan shown in C. (M and N) Fluorescent microscopy images of  
805 LP14 lung tissue blocks. Red is SARS-CoV-2 anti-sera and blue is Hoechst nuclear stain. Scale  
806 bars 100 μM (M) and 25 μM (N).

807

808 **Figure 3.** Male genital tract signal in LP14. (A, B, and C) PET/CT images highlighting the lower  
809 abdomen of LP14 from the whole-body scan. Front (A) rotated 45° (B), and side (C) views are all  
810 shown. Right and left labeled in front view. Red arrow in B and C shows location of baculum in  
811 CT scan. (D and E) PET signal with CT overlay removed to highlight signal in MGT, front (D) and  
812 side (E) views shown. (F, H, and J) Isolated 3D volume of MGT from whole body scan overlaid  
813 with CT images. Side (F) rotated 45° (H), and front (J) views shown. (G, I, and K) Isolated 3D  
814 volume of MGT used in overlays (F, H, and J) shown with same views. (L) Overlay of single z-  
815 plane of PET signal from organ scan onto image of testis of LP14. (M) PET signal from single z-  
816 plane of organ scan used in (L). (N) Image of LP14 testis used in (L). (O) 3D volume of PET signal  
817 from organ scan of single testis in previous panels.

830 obtained 3-hours after probe administration. Front view (A) and side (B) both shown. (C and D)  
831 Whole-body PET/CT scans of IN22 obtained 21-hours after probe administration. Front view (C)  
832 and side (D) both shown. Right and left labeled in front views (A and C). (E) Organ tray post  
833 necropsy and (F) PET/CT image. (G) Second organ tray post necropsy and (H) PET/CT image. (I)  
834 Overlay of PET signal onto photograph of tissue cassettes.

835

836 **Figure 6.** IN22 lung pathology and PET signal. (A-D) Lung PET volumes were isolated and  
837 overlaid on whole body CT scans. (A and B) Show lung volumes from 3-hour scan, side (A) and  
838 front (B) views shown. (C and D) Show lung volumes from 21-hour scan, side (C) and front (D)  
839 views shown. (E and F) Isolated lung PET volumes for each scan are shown independent of CT.  
840 (G) Sagittal z-slice from CT showing lungs. (H) PET signal overlaid on z-slice from G. (I)

841 Transverse z-slice through torso from CT. (J) PET signal overlaid on z-slice from I. (K) Image of  
842 respiratory tract after necropsy. (L) Inset showing overt lung pathology in right lower lobe. (M)  
843 PET/CT signal from organ scan of respiratory tract. (N) PET/CT signal from M overlaid onto  
844 image from K. (O) PET/CT signal with CT contrast increased to observe pathology in lower right  
845 lung lobe. (P) H&E image of lung tissue showing areas of expanded alveolar space and  
846 inflammatory infiltrate (arrows). (Q) Immunofluorescence image of the same tissue from P.  
847 Green is SARS-CoV-2 anti-sera, red is background, and white is nuclear stain. White arrows  
848 indicate SARS-CoV-2 positive cells. (R) H&E image of lung tissue showing macrophages and  
849 neutrophils (arrowheads) and type II pneumocytes (arrows). (S) Immunofluorescence image  
850 showing infected cells of the alveoli (arrows) and lining the alveolar septa (arrowheads). Green  
851 is SARS-CoV-2 anti-sera, red is background, white is nuclear stain. All scale bars are 100  $\mu$ M. (T)  
852 Fluorescent microscopy image of IN22 lung tissue. Spike shown in green, nucleocapsid shown in  
853 red, background in white, and Hoechst nuclear stain in blue. Scale bar 100  $\mu$ M. (U, Y, W)  
854 Additional fluorescent microscopy images of lung tissue showing foci of infected cells. U and W  
855 are shown in low magnification Y. Green is SARS-CoV-2 anti-sera and blue is Hoechst nuclear  
856 stain. Scales bar 500  $\mu$ M. (X-Z) Validation of dual antibody staining utilizing spectral imaging. (X)  
857 shows microscopy of J2 antibody with RedX secondary and rabbit anti-NC monoclonal ( ) and  
858 Cy5 secondary. (Y) Shows area within green square in X. White arrows point to regions of  
859 interest that are cell associated. Grey arrows indicate control regions of spectral evaluation.  
860 The areas evaluated by spectral imaging in (Y) are color coded and match with the spectra  
861 shown in (Z).  
862

863 **Figure 7.** Male genital tract signal in IN22. (A and B) PET/CT images highlighting the lower  
864 abdomen of IN22 obtained 3-hours after probe administration. Front view (A) and side (B) both  
865 shown. (C and D) PET/CT images highlighting the lower abdomen of IN22 obtained 21-hours  
866 after probe administration. Front view (C) and side (D) both shown. (E and F) Isolated 3D  
867 volume of MGT from 3-hour scan overlaid with whole-body CT. Side (E) and front (F) views  
868 shown. (G and H) Isolated 3D volume of MGT from 21-hour scan overlaid with whole-body CT.  
869 Side (G) and front (H) views shown. (I and J) Whole-body CT images of lower abdomen, red  
870 contours outline the testicles and spermatic cords. Front (I) and side (J) views shown. (K and L)  
871 3D volume of MGT overlaid onto CT images from previous panels. (M) Image of testicles after  
872 necropsy. (N) PET signal from organ scan of testicles. (O) Overlay of PET signal onto image from  
873 panel M. (P) Overlay of PET signal onto CT signal from same scan. White asterisks mark location  
874 of pampiniform plexus in all previous panels. (Q and R) Fluorescence microscopy of SARS-CoV-2  
875 infected cells in testicular tissue from IN22. Red is SARS-CoV-2 spike, green is SARS-CoV-2  
876 nucleocapsid, white is background, and blue is Hoechst nuclear stain. Insets show channels  
877 independently, larger image is all channels merged. Scale bars 10  $\mu$ M (S) Fluorescent  
878 microscopy image of corpus cavernosum tissue from an uninfected animal showing ACE2  
879 staining in red, background in green, and Hoechst nuclear staining in blue. Scale bar 100  $\mu$ M (T)  
880 Fluorescence microscopy of SARS-CoV-2 infected cells in penile tissue from IN22. White is  
881 dsRNA antibody J2, red is SARS-CoV-2 nucleocapsid, green is background, and blue is Hoechst  
882 nuclear stain. (U, V, and W) Show individual cells highlighted in T.  
883

884 **Figure 8.** JF82 PET/CT images from week and week 2 necropsy scans. (A and B) Whole-body  
885 PET/CT scan of JF82 from 1-week post-infection. Front view (A) and side (B) both shown. (C and  
886 D) Whole-body PET/CT scans of JF82 2-weeks post infection. Front view (C) and side (D) both  
887 shown. Right and left labeled in front views (A and C). (E and F) Overlay of the week 1 scan  
888 (shown in red) and the week 2 scan (shown in blue). Front (E) and side (F) views both shown.  
889 (G) Organ tray post necropsy and (H) PET/CT image. (I) Second organ tray post necropsy and (J)  
890 PET/CT image. (K) Overlay of PET signal onto photograph of tissue cassettes.

891

892 **Figure 9.** JF82 lung pathology and PET signal from two timepoints. (A-D) Lung PET volumes were  
893 isolated and overlaid on whole body CT scans. (A and B) Show lung volumes from 1-week scan,  
894 side (A) and front (B) views shown. White asterisk indicates location of lung pathology  
895 highlighted below. (C and D) Show lung volumes from 2-week scan, side (C) and front (D) views  
896 shown. (E and F) Isolated lung PET volumes for each scan are shown independent of CT. (G and  
897 H) Overlay of single z-image of PET signal onto single z-image of CT in the lungs at week 1 (G)  
898 and week 2 (H). (I and J) Single z-image of CT used in G and H shown independent of PET signal  
899 for week 1 (I) and week 2 (J). (K) Overlay of week 1 (shown in red) and week 2 (shown in blue)  
900 PET signal. (L) Overlay from K shown with CT image to localize PET signal. Insets above show,  
901 CT, week 1, and week 2 signal from left to right. White asterisk indicates location of left lung  
902 pathology in all panels.

903

904 **Figure 10.** Male genital tract signal in JF82. (A and B) Front view PET/CT images highlighting the  
905 lower abdomen of JF82 at 1-week (A) and 2-weeks (B). (C) Overlay of week 1 (shown in red) and

906 week 2 (shown in blue) PET signal. (D and E) Side view of same images shown in A and B. (F)  
907 side view of overlay shown in C. (G and H) Isolated MGT volume from week 1 scan. Back (G) and  
908 side (H) views shown. (I and J) Isolated MGT volume from week 2 scan. Back (I) and side (J)  
909 views shown. (K, L, and M) Isolated MGT volume from week 2 with isolated penile and  
910 testicular signal. Back (K), rotated 45° (L), and side (M) views shown. (N) H&E stain of JF82  
911 testicular tissue. Degenerate seminiferous tubules highlighted in black oval. Scale bar 500 μM.  
912 (O) Fluorescent microscopy shows a similar area of degenerate tubules. Green is CD206, red  
913 caspase 3, and white nuclear stain. Scale bar 500 μM. (P) Higher magnification image of  
914 degenerate tubules. Intraluminal macrophages (arrowheads) and Sertoli cells (arrows) are  
915 shown inside tubules. Scale bar 50 μM (Q) Higher magnification of image in O shows Sertoli  
916 cells (arrow) staining with caspase 3 and macrophages (arrowhead) staining with CD206. Scale  
917 bar 50 μM. (R) Fluorescent microscopy image showing degenerate tubule full of intraluminal  
918 macrophages. Red is caspase 3, green is CD206, and blue is nuclear stain. Scale bar 50 μM. (S)  
919 Lower magnification microscopy image of degenerate and healthy tubules. Red is caspase 3,  
920 green is CD206, and blue is nuclear stain. Scale bar 200 μM. (T and U) Fluorescent microscopy  
921 images of infected cells in testicular tissue of JF82. White is SARS-CoV-2 anti-sera, red is NSP8,  
922 green is nucleocapsid, and blue is Hoechst nuclear stain. Insets show individual channels, larger  
923 image is merge. Scale bars 10 μM.

924

925 **Figure 11.** Comparison of SUVs across animals and timepoints. (A-D) Complete rotation series of  
926 lung PET volumes for LP14 (A), IN22 (B), JF82 week 1 (C), and JF82 week 2 (D). (E-H) Front,  
927 rotated 45°, and side views of MGT PET volumes for LP14 (E), IN22 (F), JF82 week 1 (G), and

928 JF82 week 2 (H). (I-K) Front and side views of whole-body scans, white lines indicate volumes  
929 taken for heart and lungs for LP14 (I), IN22 (J), and JF82 week 1 (K). Insets show each image  
930 without white outlines. (L) Total SUVs for whole-body scans and each individual volume isolated  
931 displayed in graph. Animals are indicated by icon shape and volumes by color.

932

933 **Figure 12.** Comparison of prostate and penile signal between animals. (A-F) PET/CT signal in  
934 lower abdomen for each animal at 1-week post-infection. LP14 front (A) and rotated 45° (B),  
935 IN22 front (C) and rotated 45° (D), JF82 front (E) and rotated 45° (F). Asterisks mark location of  
936 prostate. Insets show sagittal z-slice of each animal highlighting prostate signal (white circle).  
937 (G-I) PET/CT volume of penis for IN22. Front (G) rotated 45° (H), and side (I) views shown. (J-L)  
938 PET/CT volume of penis for JF82 at 2-weeks post-infection. Front (J) rotated 45° (K), and side (L)  
939 views shown. (M) PET/CT signal of IN22 penis after necropsy. (N) PET/CT signal of JF82 penis  
940 after necropsy. (O) PET/CT signal overlaid onto an image of tissue cassettes (P) containing  
941 penile tissue of IN22. (Q) PET/CT signal overlaid onto an image of tissue cassettes (R) containing  
942 penile tissue of JF82. (S-U) H&E images of testicular tissue from each animal. LP14 (S) and IN22  
943 (T) shows normal spermatogenesis and tissue architecture. IN22 (U) shows degenerate tubules  
944 (asterisks) interspersed among healthy tubules. Scale bars all 500 μM.

945

946 **Figure 13.** PET signal associated with the pampiniform plexus. (A) Labeled dissection showing  
947 anatomical structure of a macaque testis. (B) CT image of testes and associated image showing  
948 the matching anatomical features of the spermatic cord. (C) Inset highlighting the location and  
949 appearance of the pampiniform plexus. White asterisks mark the vas deferens in all images. (D-

950 F) Single z PET/CT images of IN22 highlighting the PET signal associated with the pampiniform  
951 plexus (yellow volume) from the frontal (D), sagittal (E), and transverse (F) plane. (G) CT image  
952 used in E to highlight signal associated with pampiniform plexus (yellow volume). (H-L) Isolated  
953 3D volumes of MGT PET signal shown from the front for IN22 (H), JF82 (J), and LP14 (L). White  
954 circles outline testes. (I, K, M) Volumes from H, J, and L rotated 45°. (N) Sagittal z-slice of PET/CT  
955 of LP14 showing right testis. (O) Frontal z-slice of PET/CT, colored lines correspond to sagittal  
956 slices shown in N, P, and R. (P) Sagittal z-slice of PET/CT showing penile tissue. (Q) Frontal z-slice  
957 highlighting the testicular tissue in white ovals. (R) Sagittal z-slice of PET/CT showing left testis  
958 of LP14. White ovals highlight signal associated with testes and not pampiniform plexus.

959

960 **Figure 14.** Principle components analysis of SUV measures. (A) Mean SUV values from isolated  
961 tissue volumes. (B) The ratio of total SUV for each tissue volume to whole-body total SUV. (C)  
962 Heat map showing clustering of tissues and parameters measured from the PET data. (D)

1163  
1164

**Figure 1. Study design and viral analysis of infected macaques.** (A) Workflow of PET/CT guided necropsy. (B) Schematic showing the study design of probe administration, PET/CT scans, and infection. (C-E) Lung lesions were consistent with prior findings in NHPs infected with SARS-CoV-2 and varied from minimal in LP14 (C), moderate in IN22 (D), and mild in JF82 (E). Insets demonstrate the inflammatory infiltrate and in IN22 and JF82, type II pneumocyte hyperplasia (arrows). (F and G) Viral load measurements for all three animals. (F) shows copies/swab of genomic N while (G) shows copies/swab of subgenomic N.

1175

**Figure 2. LP14 PET/CT guided necropsy.** (A and B) Whole-body PET/CT scans of LP14 8 days post-infection. Front view (A) and rotated 45° (B) both shown. PET signal is display as SUV. (C) Post necropsy PET/CT organ scan of LP14. (D and E) Images of tissues scanned in (C). (F) Overlay of PET signal onto photograph of small pieces of tissue in cassettes. (G and H) Lung PET signal was isolated and overlaid on whole body CT scans. Side (G) and front (H) view. (I and J) Isolated lung PET volumes used in G and H are shown independently, side view (I) and front view (J). (K and L) Single axial z-slice images of respiratory tract PET/CT signals are shown, each image represents a single z-plane from scan shown in C. (M and N) Fluorescent microscopy images of LP14 lung tissue blocks. Red is SARS-CoV-2 anti-sera and blue is Hoechst nuclear stain. Scale bars 100  $\mu$ M (M) and 25  $\mu$ M (N).

1176  
1177  
1178

1179 **Figure 3. Male genital tract signal in LP14.** (A, B, and C) PET/CT images highlighting the lower  
1180 abdomen of LP14 from the whole-body scan. Front (A), rotated 45° (B), and side (C) views are  
1181 all shown. Right and left labeled in front view. Red arrow in B and C shows location of baculum  
1182 in CT scan. (D and E) PET signal with CT overlay removed to highlight signal in MGT, front (D)  
1183 and side (E) views shown. (F, H, and J) Isolated 3D volume of MGT from whole body scan  
1184 overlaid with CT images. Side (F), rotated 45° (H), and front (J) views shown. (G, I, and K)  
1185 Isolated 3D volume of MGT used in overlays (F, H, and J) shown with same views. (L) Overlay of  
1186 single z-plane of PET signal from organ scan onto image of testis of LP14. (M) PET signal from  
1187 single z-plane of organ scan used in (L). (N) Image of LP14 testis used in (L). (O) 3D volume of  
1188 PET signal from organ scan of single testis in previous panels.  
1189

1190  
1191

1192 **Figure 4. Immunofluorescence of LP14 Testes.** (A) Fluorescent microscopy image of LP14  
1193 seminiferous tubules. ACE2 staining shown in red, Hoechst nuclear staining shown in blue. Inset  
1194 shows zoom in of single tubule to better view ACE2 staining in Sertoli and myoid cells. Scale  
1195 bars 50  $\mu$ M. (B) Fluorescent microscopy image of LP14 testis shows infected cells. SARS-CoV-2  
1196 anti-sera staining in green, background fluorescent in red, and Hoechst nuclear staining in blue.  
1197 Scale bars 25  $\mu$ M. (C) Microscopy images of two tubules containing infected cells (top and  
1198 bottom rows). Red is SARS-CoV-2 anti-sera, green is smooth muscle actin, gold is vimentin, and  
1199 blue is Hoechst nuclear stain. Possible infected germ cells marked by arrow heads. Scale bars 20  
1200  $\mu$ M.

**Figure 6. IN22 lung pathology and PET signal.** (A-D) Lung PET volumes were isolated and overlaid on whole body CT scans. (A and B) Show lung volumes from 3-hour scan, side (A) and front (B) views shown. (C and D) Show lung volumes from 21-hour scan, side (C) and front (D) views shown. (E and F) Isolated lung PET volumes for each scan are shown independent of CT. (G) Sagittal z-slice from CT showing lungs. (H) PET signal overlaid on z-slice from G. (I)

1220 Transverse z-slice through torso from CT. (J) PET signal overlaid on z-slice from I. (K) Image of  
1221 respiratory tract after necropsy. (L) Inset showing overt lung pathology in right lower lobe. (M)  
1222 PET/CT signal from organ scan of respiratory tract. (N) PET/CT signal from M overlaid onto  
1223 image from K. (O) PET/CT signal with CT contrast increased to observe pathology in lower right  
1224 lung lobe. (P) H&E image of lung tissue showing areas of expanded alveolar space and  
1225 inflammatory infiltrate (arrows). (Q) Immunofluorescence image of the same tissue from P.  
1226 Green is SARS-CoV-2 anti-sera, red is background, and white is nuclear stain. White arrows  
1227 indicate SARS-CoV-2 positive cells. (R) H&E image of lung tissue showing macrophages and  
1228 neutrophils (arrowheads) and type II pneumocytes (arrows). (S) Immunofluorescence image  
1229 showing infected cells of the alveoli (arrows) and lining the alveolar septa (arrowheads). Green  
1230 is SARS-CoV-2 anti-sera, red is background, white is nuclear stain. All scale bars are 100  $\mu$ M. (T)  
1231 Fluorescent microscopy image of IN22 lung tissue. Spike shown in green, nucleocapsid shown in  
1232 red, background in white, and Hoechst nuclear stain in blue. Scale bar 100  $\mu$ M. (U, Y, W)  
1233 Additional fluorescent microscopy images of lung tissue showing foci of infected cells. U and W  
1234 are shown in low magnification Y. Green is SARS-CoV-2 anti-sera and blue is Hoechst nuclear  
1235 stain. Scales bar 500  $\mu$ M. (X-Z) Validation of dual antibody staining utilizing spectral imaging. (X)  
1236 shows microscopy of J2 antibody with redX secondary and rabbit anti-NC monoclonal and Cy5  
1237 secondary. (Y) Shows area within green square in X. White arrows point to regions of interest  
1238 that are cell associated. Grey arrows indicate control regions of spectral evaluation. The areas  
1239 evaluated by spectral imaging in (Y) are color coded and match with the spectra shown in (Z).

**Figure 7. Male genital tract signal of IN22.** (A and B) PET/CT images highlighting the lower abdomen of IN22 obtained 3-hours after probe administration. Front view (A) and side (B) both shown. (C and D) PET/CT images highlighting the lower abdomen of IN22 obtained 21-hours after probe administration. Front view (C) and side (D) both shown. (E and F) Isolated 3D volume of MGT from 3-hour scan overlaid with whole-body CT. Side (E) and front (F) views

1248 shown. (G and H) Isolated 3D volume of MGT from 21-hour scan overlaid with whole-body CT.  
1249 Side (G) and front (H) views shown. (I and J) Whole-body CT images of lower abdomen, red  
1250 contours outline the testicles and spermatic cords. Front (I) and side (J) views shown. (K and L)  
1251 3D volume of MGT overlaid onto CT images from previous panels. (M) Image of testicles after  
1252 necropsy. (N) PET signal from organ scan of testicles. (O) Overlay of PET signal onto image from  
1253 panel M. (P) Overlay of PET signal onto CT signal from same scan. White asterisks mark location  
1254 of pampiniform plexus in all previous panels. (Q and R) Fluorescence microscopy of SARS-CoV-2  
1255 infected cells in testicular tissue from IN22. Red is SARS-CoV-2 spike, green is SARS-CoV-2  
1256 nucleocapsid, white is background, and blue is Hoechst nuclear stain. Insets show channels  
1257 independently, larger image is all channels merged. Scale bars 10  $\mu$ M (S) Fluorescent  
1258 microscopy image of corpus cavernosum tissue from an uninfected animal showing ACE2  
1259 staining in red, background in green, and Hoechst nuclear staining in blue. Scale bar 100  $\mu$ M (T)  
1260 Fluorescence microscopy of SARS-CoV-2 infected cells in penile tissue from IN22. White is  
1261 dsRNA antibody J2, red is SARS-CoV-2 nucleocapsid, green is background, and blue is Hoechst  
1262 nuclear stain. (U, V, and W) Show individual cells highlighted in T.
