ABSTRACT

Introduction The paucity of data describing cardiovascular disease (CVD) in pregnancy in many parts of Africa including Tanzania has given rise to challenges in proper management by the healthcare providers. This study is set out to (1) determine the prevalence of a range of CVDs during pregnancy in women attending antenatal clinics in Tanzania and (2) determine the impact of these CVDs on maternal and fetal outcomes at delivery.

Methods and analysis This is a cross-sectional study with a prospective component to be conducted in two referral hospitals in Tanzania. Pregnant women aged ≥18 years diagnosed with a CVD during the antenatal period are being identified and extensively characterised by performing clinical assessment, modified WHO staging, electrocardiography, echocardiography and laboratory tests. Patients identified with CVDs (exposed) and a subset without (unexposed) will be followed up to determine maternal and fetal outcomes at delivery. A minimum sample of 1560 will be sufficient to estimate the prevalence of CVDs with a 95% CI of 2.75% to 5.25%.

Ethics and dissemination The study is being conducted in accordance with the Helsinki declaration on studies involving human subjects. Ethical approvals have been obtained from Muhimbili University (reference number DA.282/298/01.C/) and Bugando Medical Centre (reference number CREC/330/2019) Ethics Committees. Informed consent is sought from all potential participants before any interview or investigations are performed. Study findings will be disseminated to the scientific community through different methods. Results will also be communicated to policymakers and to the public, as appropriate.

INTRODUCTION

The magnitude of cardiovascular diseases (CVDs) during pregnancy is increasing across the world, resulting in significant morbidity and mortality.[1–3] In high-income countries

Strengths and limitations of this study

► To the best of our knowledge, this will be the first study conducted in a large population of pregnant women in Tanzania to determine the prevalence of cardiovascular diseases (CVDs) and the effect on maternal and fetal outcomes at delivery.

► The extensive assessment of CVDs using clinical assessment and different imaging modalities will potentially capture even asymptomatic CVDs.

► The prospective follow-up of all pregnant women from antenatal visits though delivery and the systematic assessments of the mother and fetus will reduce bias in the outcome of interest.

► The extensive data generated at enrolment have the potential for future long-term follow-up research to unravel other yet unknown risk factors for maternal and fetal outcomes, including genetic studies.

► A potential limitation of this study is the identification of maternal and fetal outcomes only at delivery, thereby potentially missing some outcomes that may manifest later.

(HIC), CVDs are seen in 0.2%–4% of the pregnant women.[4 5] In contrast, the prevalence of these conditions is largely unknown in Tanzania and many parts of Africa. Aetiology and outcome of CVDs vary between low income and HIC.[1 6] In both populations, women may have pre-existing disease unmasked by pregnancy (eg, mitral stenosis due to rheumatic heart disease (RHD)), a superimposed condition unique to pregnancy (eg, peripartum cardiomyopathy) or a complication of pregnancy itself (eg, hypertensive disorders of pregnancy).

In HIC, the increasing trend of CVDs in pregnancy has been reported to be associated with a number of factors, including a shift of childbearing age towards older women who are more likely to present with CVDs of ageing and lifestyle.[7] Also, as a result of better management and increased survival of patients with congenital heart disease (CHD), there has been an increased number of pregnant women with repaired or monitored CHD.[8] In the UK, for example, cardiac diseases have become the leading cause of indirect maternal death, occurring at a rate of 2.1 per 100 000 pregnancies.[9] Ischaemic heart diseases (24%), cardiomyopathies (27%), sudden arrhythmic cardiac deaths (18%) and aortic dissection (11%) are the primary cardiac diseases in the UK, with RHD still a frequent cause of maternal death (7%), particularly in immigrants.[9]

Continued lack of awareness about maternal CVDs in Africa often leads to suboptimal care and missed opportunities during pregnancy and after delivery.[10 11] During the past decade, a steady increase in institutional maternal mortality rate for cardiac disease in Africa has been reported.[1 12] In South Africa, after non-pregnancy-related infections, cardiac disease is the second most common cause of indirect maternal death, with postpartum cardiomyopathy and complications due to RHD contributing to more than 50% of the cases.[11 12] Similar data are very limited in other parts of Africa. In Tanzania, there are no studies reporting on the magnitude of CVDs in this population as well as data on prognosis. As embodied in the Millennium Development Goals and later the Sustainable Development Goals, the death of a mother not only affects the survival of the immediate maternal period but also has effects throughout the life course of the child as well as the next generation.[13 14]

A number of registries and contemporary analyses of pregnancy outcomes of women with heart diseases have been reported in the literature (table 1). Of note, more recent results from the large EURObservational Research Programme Registry of Pregnancy and Cardiac disease registry have added to our understanding of the maternal and fetal outcomes of women with different cardiac conditions, including women with uncorrected CHD,[15] transposition of great arteries,[16] aortic coarctation[17] and in those with ischaemic heart disease.[18] Most of these studies are predominantly from HIC, and many have focused on women with CHD[15–17 19–21] as well as in general CVDs.[2 3 18 22 23] Although the majority of studies have reported an increased risk of adverse maternal and fetal outcomes,[3 15 19 20 22–26] others did not show this increased risk.[2 21 27] In Australia, Sartain et al found RHD to have impact on maternal cardiac outcomes only in those with high predictable risks, and they report no maternal or fetal mortality in their cohort of 54 pregnant women with RHD.[27] However, RHD was associated with an increased maternal and fetal adverse outcomes in studies from Egypt[26] and China.[28] In South Africa, Sliwa et al[29] showed a disease pattern markedly different to that seen in HIC with RHD, cardiomyopathies, coronary heart disease and some previously not diagnosed CHD as being major problems, often complicated by HIV/AIDS as a comorbidity. The data also demonstrated a significantly higher maternal mortality rate (5.9%) among pregnant women with CVDs compared with 1% in a study of a similar population conducted in Europe.[2]

CVDs in pregnancy have not been well studied and characterised in Africa. Availability of more data and establishment of regional registries from this continent aim to accumulate evidence for the development of locally acceptable treatment guidelines and possible reduction of maternal morbidity and mortality, resulting in better fetal outcome.

Study rationale

The burden, characteristics and short-term prognosis of CVDs on pregnancy have been fairly studied in HIC but considerably less in developing countries and are largely unexplored in many parts of Sub-Saharan Africa, including Tanzania. This study is expected to contribute to our understanding of the magnitude and possible uniqueness of the clinical patterns of CVDs in pregnant women in Tanzania, and their short-term prognosis. Such knowledge is essential in the prevention and treatment of CVDs in pregnancy. The data generated may also provide evidence for the development of locally acceptable management guidelines.

The study may also create awareness for active screening of these CVDs in pregnancy and possibly lead to improvement in maternal and fetal outcomes at delivery. In addition, targeting the risk factors associated with poor outcomes will have a positive impact on preventive measures.

Finally, the study will lay a platform for establishing a national/regional maternal CVDs registry in Tanzania and East Africa, in which evidence-based treatments/practices can be agreed on, implemented, and the natural history of these conditions is closely monitored.

Research questions

1. How common are CVDs among pregnant women in Tanzania?
2. Are the clinical presentation of pregnant women with CVD different from those women without CVD?
3. Are maternal and fetal outcomes at delivery worse for pregnant women with CVD compared with those without CVD?

Study objectives

The primary objectives of this study are:
1. To determine the prevalence of CVDs among pregnant women visiting their antenatal clinics (ANC) in Tanzania.
2. To describe (as determined by clinical, electrocardiographic, echocardiographic parameters and WHO risk stratification) the types of CVDs observed in pregnant women visiting their ANC in Tanzania.

Table 1 Examples of studies with reports on maternal and fetal outcome in pregnant women with heart diseases

CHD, congenital heart disease; HELLP, Hemolysis, Elevated Liver enzymes and Low Platelets; RHD, rheumatic heart disease.

The secondary objectives are:
1. To compare the incidence of a composite of maternal adverse clinical outcomes (MACO) (all cause death, mode of delivery—caesarean section, heart failure, eclampsia and obstetric haemorrhage requiring admission) in pregnant women presenting with CVDs versus without CVDs at their ANC and followed-up prospectively to delivery.
2. To compare the incidence of a composite of fetal adverse clinical events (FACE) (fetal death, prematurity, intrauterine fetal growth retardation, birth weight and respiratory distress) at delivery in pregnant women presenting with CVDs versus without CVDs (as diagnosed at baseline).

METHODS AND ANALYSIS
Study design
This will be a hospital-based cross-sectional study with a prospective component to be conducted in two centres

Figure 1 Study design of cross-sectional and prospective components. BMC, Bugando Medical Centre; ECHO, echocardiogram.

as illustrated in figure 1. The two sites are selected to be representative of the urban and rural populations in Tanzania.

Study setting, antenatal and CVDs services in Tanzania

The study will be conducted in the ANC and Cardiac units of the two main referral Hospitals in Tanzania, namely, Muhimbili National Hospital in Dar es Salaam and Bugando Medical Centre in Mwanza located at a distance of over 1100 km (from Dar es Salaam). Dar es Salaam is composed of urban diverse ethnic groups compared with Mwanza, a cosmopolitan city with mixture of different ethnic rural groups.

Muhimbili National Hospital is a national and teaching hospital located in the largest City of the Country, Dar es Salaam region, serving mainly the urban and the referred populations. The hospital has ANC services and is closely linked to cardiology services at Jakaya Kikwete Cardiac Institute, within the same campus. An average of 80 pregnant women attend the clinic daily, and 80% of them attend in view of their current pregnancy while 20% are post-natal follow-ups.

Bugando Medical Centre is the second referral consultant and University Teaching Hospital in Tanzania. It is a referral centre for tertiary specialist care for eight regions and serves a catchment population of approximately 18 million people. It mainly serves a rural population. The hospital has both antenatal clinic and cardiology clinics. About 80 pregnant women attend the clinic daily, which is run on 5 days a week. At each clinic, up to 30 pregnant women per day are attending for their first time.

As per National guidelines, pregnant women in Tanzania are required to start ANC visits as soon as possible in the first trimester of pregnancy (though many of them come at different stages of pregnancy) and are followed-up to delivery.

Study duration

The first participant was enrolled in October 2019 and we expect the follow-up of the last enrolled participant to end in May 2021.

The inclusion and exclusion criteria are presented in table 2.

Power calculations and sample size

Assuming the prevalence of CVDs in pregnant women to be as high as the 4% reported in HIC,[4 5] then a sample size of 945 will be sufficient to estimate the prevalence of CVDs with a 95% CI of 2.75% to 5.25%. Recruitment

Table 2 Study population, inclusion and exclusion criteria

Inclusion criteria	Exclusion criteria
Pregnant women attending the ANC	Women not residing in Dar es salaam or Mwanza
Age≥18 years	Women with known diabetes, sickle cell anaemia, asthma, coagulation disorders, advanced HIV stage (III–IV) and advanced renal failure
	Refusal to give informed consent

ANC, antenatal clinics.

will be from one rural and one urban site, thus the prevalence of CVDs could vary by site and so to account for this, by assuming a design effect of 1.5% and 10% loss to follow-up, a minimum sample size of 1560 will be enrolled.

Case definition
1. A CVD event will include any/combinations of the following; known hypertensive or newly diagnosed hypertension, defined as systolic blood pressure ≥140 mm Hg and/or diastolic blood pressure ≥90 mm Hg on three readings, known or newly diagnosed RHD, any other valvular disease, CHD, known or newly diagnosed cardiomyopathies, coronary heart disease, heart failure, pericardial disease (ie, tuberculosis), arrhythmias—atrial fibrillation/flutter, ventricular fibrillation and bundle branch block (2nd–3rd degree).
2. Heart failure as per European Society of Cardiology (ESC) diagnostic criteria.[30]

Primary endpoints
Prevalence of CVDs in pregnant women visiting ANC in Tanzania

Secondary endpoints
1. Incidence of a composite of MACO, defined as at least one of the followings: all cause deaths, heart failure, caesarean mode of delivery, eclampsia and obstetric haemorrhage requiring admission in pregnant women.
2. Incidence of a composite of FACE, defined as at least one of the followings: fetal death, prematurity, low birth weight and respiratory distress in the baby.

Study protocol
Initial assessment of pregnant women at the ANC
Every sampled pregnant woman ≥18 years at any gestation age visiting the ANC will be given opportunity to consent her participation into the study, as shown in figure 2.

Clinical assessment and measurements (at the ANC)
At the ANC, all consenting eligible consecutive pregnant women will be interviewed and examined for sociodemographic and baseline clinical characteristics such as age, education level, occupation, blood group, history of any CVDs, smoking and alcohol consumption, chronic hypertension, HIV status, gestation age, parity, prior surgery or cardiac intervention, use of medication and known/documented comorbidities such as renal disease, and diabetes.

Cardiological examination
At the cardiology clinic, detailed examination of the CVDs will include both ECG and an echocardiogram (ECHO) examination for all recruited women. Women with CVDs will be further stratified into four risk groups using a modified WHO risk classification for pregnant women with cardiac disease (figure 3). The WHO risk stratification tool is based on the disease severity and has a prediction value in the management of pregnant women. Depending on the diagnosis and severity of the disease, risk classification will range from class I (low risk) to class IV (contraindication for pregnancy), as used in the ESC Guidelines on the management of CVD during pregnancy.[4]

Haematological evaluation and serum storage
In all eligible pregnant women, blood will be collected for full blood count. The serum will be stored with the consent of participants, for up to 10 years after study completion for further tests (including genetic studies related to CVD or pregnancy) that may emerge in the future.

Electrocardiography and echocardiography measurements
A standard 12-lead ECG will be obtained in all eligible pregnant women referred to the cardiology unit from the ANC, being in supine position, in a quiet room, using

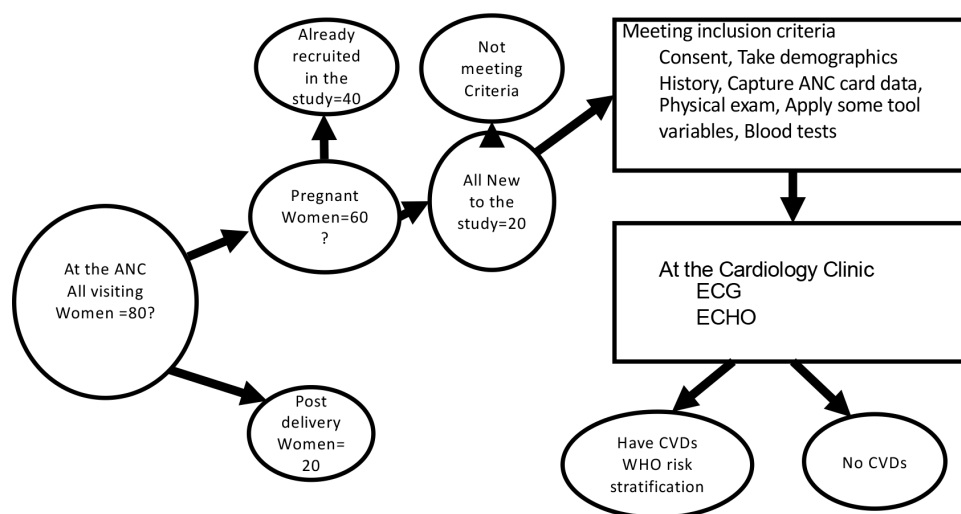

Figure 2 Weekly flow of pregnant women-identification and enrollment of participants. ANC, antenatal clinics; CVD, cardiovascular disease; ECHO, echocardiogram.
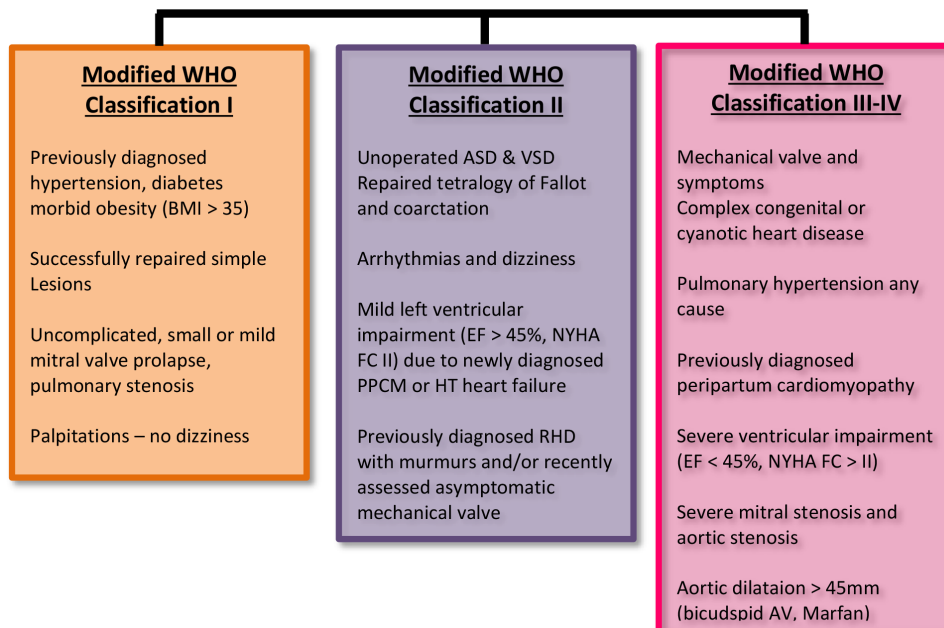

Modified WHO Classification I	Modified WHO Classification II	Modified WHO Classification III-IV
Previously diagnosed hypertension, diabetes morbid obesity (BMI > 35)	Unoperated ASD & VSD Repaired tetralogy of Fallot and coarctation	Mechanical valve and symptoms Complex congenital or cyanotic heart disease
Successfully repaired simple Lesions	Arrhythmias and dizziness	Pulmonary hypertension any cause
Uncomplicated, small or mild mitral valve prolapse, pulmonary stenosis	Mild left ventricular impairment (EF > 45%, NYHA FC II) due to newly diagnosed PPCM or HT heart failure	Previously diagnosed peripartum cardiomyopathy
Palpitations – no dizziness	Previously diagnosed RHD with murmurs and/or recently assessed asymptomatic mechanical valve	Severe ventricular impairment (EF < 45%, NYHA FC > II)
		Severe mitral stenosis and aortic stenosis
		Aortic dilataion > 45mm (bicudspid AV, Marfan)

Figure 3 Modified WHO risk stratification. RHD, rheumatic heart disease.

PHILIPS machine (Pager, Trim III). Recording will be done with standard ECG paper at a speed of 25 mm/s and calibration of 10 mm/mV standardisation.

Echocardiography will be initially performed in every pregnant woman prior to assigning into 'exposed/unexposed' groups using General Electric Vivid V.5 with a 2.5–5 MHz probe Trans-thoracic, M-mode, two-dimensional and tissue Doppler imaging (TDI) by an experienced echocardiographer. The focus will be on assessment of both the left ventricular dimensions and function. In particular, diastology will be an important aspect of the comprehensive echocardiographic assessment of these patients. Echocardiographic indices of diastolic dysfunction will include TDI, mitral diastolic flow profile and increased left atrial filling pressures.[31] The ECG/ECHO findings will be interpreted by the author, reviewed and approved by a second senior and experienced cardiologist (A).

Storage of ECG and ECHO data and independent evaluation of interpretation

Data on ECG and ECHO will be stored in hard disks/Compact Discs (CDs) in an access-controlled area, and it will be easily retrieved and backed up to allow an independent evaluation of 15% of the cases by another experienced cardiologist (B). In case of disagreement of the findings between (A) and (B), a third senior consultant cardiologist (C) will be asked to review the ECHOs and provide the conclusion, taking into consideration both the clinical presentation and the ECHO findings.

Inter observer variations in ECHO measurements

As the ECHO machines are of similar General Electric (GE) models, the sonoechocardiographers will be trained on standardised image acquisitions, and we will perform monthly quality control for the two sites.

The follow-up sub-study

The study will involve follow-up of all pregnant women identified with CVDs versus a subset of those without, for MACO and FACE at delivery. Pregnant woman's CVD/no-CVD status will be defined at enrolment, and any incident CVD during the follow-up period will not count for the purpose of assigning participants into the two groups. However, any incident CVD event will be documented on the case report forms (CRF).

Selection of exposed patients

All pregnant women identified with CVDs in the main study will be selected and considered as exposed patients.

Selection and matching of a subset of unexposed participants

Pregnant women identified without CVD events in the main study will form a pool of unexposed (figure 4). Matching by age (±5 years) and gestation age (rounded to 1 month) will be applied to identify the unexposed, two times the number of cases using simple random numbers generated using preset seeds. For each exposed case identified, a list of pregnant mothers meeting the criteria for matching with the index case will be prepared from which unexposed pregnant women will be selected. The unexposed participants will be selected if the list contains at least three times the number of each index exposed case, otherwise, unexposed women will be selected among the pool of unexposed individuals in the next clinical visit. Unexposed women (among those not yet delivered) will be selected immediately on identification of the corresponding exposed women.

Women whose pregnancies are terminated for any reason before delivery will have no further follow-up, but information on termination will be kept as an additional outcome measure.
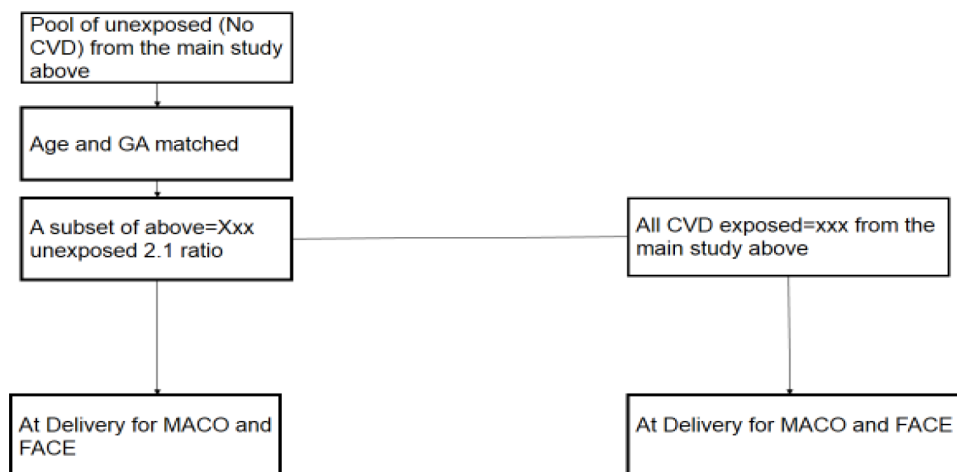

Figure 4 Identification of exposed and unexposed women and outcomes at delivery. CVD, cardiovascular disease; FACE, fetal adverse clinical event; MACE, major adverse cardiac event.

Follow-up and assessment of secondary endpoints

Clinical follow-up visits will be performed at delivery to establish any events of MACO and FACE (table 3). For participants who will not deliver at the recruiting hospital, follow-up data will be obtained by making phone contacts and physical follow-up (at the hospital of delivery) by a research nurse and study coordinators. Also, all enrolled mothers will be encouraged to receive their health services at the index hospital. In case of attendance elsewhere, they should have a phone number for the research clinician and nurse to send the message for any event, leading to birth (ie, labour).

A research nurse will make monthly phone follow-up calls to all women with CVDs and a subset of those without (unexposed), until delivery to maintain a close contact with our team and determine whether there is any change in the expected date/place of delivery. Once mothers are admitted in labour, they will be encouraged to send message/calls to the research nurse. The research team will also arrange with the labour ward nurses to be contacted anytime a mother recruited into the study (determined by an identifiable study label on antenatal card) is admitted to the ward for delivery. Once contacted, the research nurse will follow-up the mother on the ward and precisely capture the maternal and fetal outcomes. Additionally, study nurses will visit the labour wards of the two hospitals daily to actively identify any study participant in labour.

Handling loss to follow-up

All pregnant women will be asked to provide their phone contacts as well as those of two close relatives/neighbours to ensure effective communication, including being unable to report for delivery at the primary hospitals.

Data analysis plan

Database management and statistical analyses will be performed with STATA software, V.13 and using the statistical software R (https://cran.r-project.org/). Continuous data will be expressed as mean±SD if normally distributed or median with range/IQR if non-normally distributed. Comparison of means and proportions between subgroups at baseline will be performed using the Student-t, χ^2 Fisher's or Wilcoxon rank-sum test statistics where appropriate. Categorical variables (primary and secondary) will be summarised using frequencies and percentages. Independent t test will be performed on secondary measures. The association between binary secondary response variable (eg, MACO) and independent predictors will be assessed using logistic regression model. The study secondary endpoints (MACO and FACE) will be taken as composite endpoints, and they will

Table 3	Visit/data collection measurement schedule		
Variable	**At enrolment**	**During follow-up in between**	**At delivery**
Informed consent	X	Passive screening—2 weekly by a doctor or woman on demand	
Inclusion/exclusion criteria	X		
Demographics	X

Physical examination	X		X
Medications	X		
Full blood picture	X		
ECG and ECHO	X		
Outcome events— MACO and FACE			X

To be collected in all exposed women (with CVDs) and in a subset of unexposed women (without CVDs).
CVD, cardiovascular disease; ECHO, echocardiogram; FACE, fetal adverse clinical event; MACE, major adverse cardiac event.

not be detailed for their separate diagnoses due to the limited sample size. Continuous variables will be assessed for normality assumptions, and where required, appropriate transformation will be done, and their association with independent predictors will be assessed using linear regression model. Interaction between independent variables will be explored during assessment of model adequacy. Statistical significance is defined as $p < 0.05$. The analysis will follow a prespecified statistical analysis plan.

Data management

Data will first be captured on paper CRFs designed for the study, then entered into a specifically developed web-based (REDCap) platform for this project, at both sites. For quality control purposes, there will be double data entry with checks in 15% of the CRFs.

If a participant withdraws from the study, all medical record information related to her/him will be destroyed only if the participant asks that all information be withdrawn. If a participant does not request that all their information be destroyed, but to withdraw from future participation only, then any information collected prior to the withdrawal will be maintained. The principal investigator (PI) will be responsible for ensuring that the data collected are complete, accurate and recorded in a timely manner.

Data security and confidentiality

All consent forms will be kept in a locker (with a lock and Key) in the consent room. All patients will receive a study ID and the corresponding name only known to the site coordinator. The consent forms and CRFs will be collected by the site PI from the lockers to Muhimbili University (MUHAS) office where they will be stored. The exposed to the corresponding non-exposed will be linked through a unique ID number. The confidentiality of study participants will be protected by randomly assigning individual identifiers, which will be linkable to identifying information. All data will be anonymised.

Ethical considerations

Ethical approval has been obtained from the MUHAS (reference number DA.282/298/01.C/) and the Bugando Medical Centre (reference number CREC/330/2019) Ethics Committees. Informed consent (signed or thumb-printed) is being sought from all potential participants before any interviews or investigations are performed. Refusal to participate in the study does not, in any way, affect the management of the patient. Individuals who are not eligible for inclusion into the study are being referred back to their health facility for follow-up or are seen at the cardiac clinic as per normal protocols. Withdrawal from the study at any time lies within the participant's discretion and does not hinder the individual's right to appropriate healthcare. As the ANC is closely linked to cardiac clinic in the same hospital, women with CVDs are followed-up at the same cardiac clinic as per standard of care. Consent and ethical approval are sought from

the study participants for storing the serum for 10 years after the study, or future tests (including genetic studies related to CVD or pregnancy). Personal and medical information identifying the participant (with the sample) are kept confidential.

Plans for dissemination of research findings

The findings will be disseminated in several forms (a) feedback research reports to the health facility sites and to the funder GlaxoSmithKline (GSK), (b) faculty symposium, research reports and journal club presentation in the participating hospitals, (C) research reports to the Ministry of Health in Tanzania, (d) abstract presentation in local and international conferences, (e) university website announcement, (f) journal publications, (g) public release notification in media and research bulletin.

Potential risks and mitigation plans

Both ECG and ECHO investigations are non-invasive and carry no potential risk to the participants. During drawing of blood, participants may experience mild pain and/or swelling at the puncture site, and occasionally the puncture site could be infected. To minimise any risk, research nurse assistants have been trained on proper and sterile blood drawing procedures as well as trained to adhere to infection prevention and control procedures.

Patients and public involvement

Participants of this study gave their feedback regarding the data collection tools as part of their participation in the study. Feedbacks were given after data piloting
