This experiment was to investigate the age-related changes in hormonal concentration and biochemical constituents of blood plasma in Indian native desi fowl. One hundred and sixty two (54 from each breed, i.e., Kadaknath (KN), Aseel peela (AP), and White leghorn (WLH)) day-old female chicks were randomly divided into nine groups each of 18 chicks (3 groups × 3 replicates). WLH was taken in this study to compare the characteristics of Indian native desi fowl. The highest level of estrogen hormone in WLH and desi fowl in blood plasma was occurred at 18 and 24 wks of age, respectively. Whereas, the peak of progesterone hormone in WLH hens noticed around 24 wks, in case of desi fowls, it was at 30 wks of age. Irrespective of the breed, the hormonal profile of Triiodothyronine (T3) and Thyroxine (T4) in blood plasma was found highest around 6 to 12 wks of age. Activities of acid phosphatase (ACP) increased with the reduction of alkaline phosphate (ALP) activities at different time intervals. Irrespective of the breed, transaminases (glutamic oxaloacetic transaminase (GOT) and glutamic pyruvic transaminase (GPT)) activities of blood plasma increased linearly with the advancement of the age. From this study, it may be concluded that sexual maturity of the Indian native desi fowl occurred nearly 6 wk later (24 wk) than WLH.

1. Introduction

According to FAO [1], population of India is expected to increase from 1.03 billion in 2003 to 1.35 billion in 2025. To feed rapid growing of human population and to fight against malnutrition, there is need to produce sufficient amount of meat and eggs. National Advisory Committee has recommended annual consumption of 180 eggs, at the rate of half egg per day per person and 9 kg of poultry meat per year at the rate of approximately 25 gm meat every day. However, at present its availability is only 45 eggs and 1.60 kg of poultry meat, respectively. The wide gap, therefore, exists between demand and supply of eggs and meat for our nutritionally starved masses need to be bridged through poultry in which desi fowl can play a very important role because that is the back bone of our rural poultry production and constituting nearly 70% (Kadaknath, Aseel, etc.).

Kadaknath (KN) and Aseel Pela (AP) are the Indian native fowl which are well known for poor egg production

(120–140 eggs/laying cycle), slow growth, frequent broodiness, smaller body size (1.2–1.5 kg in adult), small egg size (40–42 g), and late sexual maturity. Eggs and meat production in birds is regulated by several complex interactions in which avian reproduction played an important role. This area of science is totally neglected and uninvestigated in desi fowl. The hormonal profile and reproductive development of desi fowl from postnatal to adult stage (age-dependent development) is not known. Knowledge gained from this could be used for neuroendocrine manipulation, which is a popular tool for improving egg production through hormone administration. It is hypothesized that slow maturation of ovary and oviduct in desi fowl (Kadaknath and Aseel peela) occurs up to 18 to 19 weeks of age.

Numbers of studies have been done to understand the relationship in exotic breed [2–4], but studies on Indian native fowl (KN and AP) are lacking. So, this study described here attempted to know the age-related changes in hormonal

concentration and biochemical composition in blood plasma of Indian native fowl.

2. Materials and Methods

2.1. Experimental Stock. More than one hundred fertile eggs from each breed, that is, Kadaknath (KN), Aseel peela (AP), and White Leghorn (WLH) were procured from the experimental layer farm, and the eggs were hatched at Institute's hatchery. WLH was taken in this study to compare the characteristics of Indian native desi fowl. One hundred and sixty two (54 from each breed) day-old female chicks were randomly divided into nine groups each of 18 chicks (3 groups \times 3 replicates). The day-old chicks were housed on floor, covered with litter, and maintained under uniform husbandry conditions. They were given normal rations (21% crude protein, 2,900 Kcal/kg ME, 3% total calcium and 0.5% total phosphorus) as per the requirement of particular age group and water *ad libitum* with a constant light 14 hrs/day throughout the experiment. Mortality as and when occurred is recorded. All the experiments were conducted strictly in accordance with the guideline of Institutional Animal Ethics Committee (IAEC).

2.2. Blood Collection. Blood samples were collected (2 mL) from all the birds through wing vein from 6th week to 30th week. Heparin at the rate of 5 IU/mL was used as anticoagulant. The blood was centrifuged at 2500 rpm for 10 minutes to separate the plasma for estimation of hormones (estrogen, progesterone, Triiodothyronine (T₃), and Thyroxine (T₄)) and biochemical constituents. Plasma samples were stored at -40°C till use.

2.3. Estimation of Hormones. Plasma estrogen, progesterone, T₃, and T₄ concentration were determined using ELISA kits (Dia Metra, USA). The absorbance was recorded by using Spectramax. The hormones concentration was determined by plotting OD of samples against the standard graph. Performed the hormone examination in all the three breeds, that is, KN, AP, and WLH in every six wks interval from 6th to 30th wks.

2.4. Estimation of Phosphatases and Transaminases. Acid phosphatase (EC 3.1.3.2, ACP) was analysed by using the method as described by Andersch and Szcypinski [5] and Alkaline phosphatase (EC 3.1.3.1, ALP) was examined by method of Bessay and Lowry [6]. Glutamic oxaloacetic transaminase (EC 2.6.1.1 GOT) and Glutamic pyruvate transaminase (EC 2.6.1.2, GPT) were estimated by Reitman and Frankel [7] method by using the kits supplied by Qualigens Diagnostics.

2.5. Statistical Analysis. Data were analyzed using statistical software package developed at the Computer Centre of Central Avian Research Institute and followed standard procedures for ANOVA [8] and Duncan's multiple range tests [9] by comparing means for significant differences.

3. Results

3.1. Hormone Concentration. The age-dependent variation in the level of estrogen, progesterone, T₃ and T₄ concentration in blood plasma of different breeds of fowl is presented in Tables 1, 2, 3, 4, and 5. The estrogen profile of blood plasma in WLH hen increased significantly ($P < .05$) and rapidly with age until 18 wks and decreased subsequently. In contrast, the level of progesterone was increased slowly by the end of 18 wks and significantly ($P < .05$) increased rapidly in the following intervals then remain constant. In Indian native fowl, the peak of estrogen hormone exhibited nearly 6 wk later (24 wks) than WLH. After 24 wks the reduction of estrogen level associated with increase in the level of progesterone. Within the desi fowl at all intervals the hormonal profile of estrogen and progesterone was found higher in KN than AP. Both the hormones T₃ and T₄ have been examined in present study in relation to age advancement associated with growth of chicken. Irrespective of breeds, the concentration of T₄ was found highest around the age of 6 wks but declined significantly ($P < .05$) until the age of 12 wks. Subsequently, T₄ concentration remained relatively stable during the following week's intervals. Within breeds, maximum profile of T₄ was examined in AP followed by KN and WLH at various intervals. However, in case of T₃, within the breed, no significant difference was found throughout the study at specific interval.

3.2. Phosphatases and Transaminases Activities. The phosphatases (ACP and ALP) and transaminases (GOT and GPT) activities in the blood plasma of different breeds are presented in Tables 1 to 5. With the advancement of age, a reverse trend was found in both the phosphomonoesterase (ACP and ALP) activities. ACP activity increases significantly ($P < .05$) with age whereas a reduction ($P < .05$) in the activity of ALP was accounted. Highest ACP activity was revealed by KN followed by WLH and AP. Regarding the ALP, the highest specific activity was expressed by the AP rather than KN and WLH. Activity of both the transaminases increased linearly throughout the study period, irrespective of the breed. Mean values of GOT of WLH at the age of 6 and 12 wk was significantly ($P < .05$) higher than two desi breeds (i.e., KN and AP) whereas the mean values of GPT of WLH remained significantly ($P < .05$) higher at all the intervals of the study period that is, 6, 12, 18, 24, and 30 wks when compared with other breeds.

4. Discussion

4.1. Hormone Concentration. The data reveals that the age around 18 wks is the transition phases, which correlates the age of initiation of sexual maturity in WLH. The similar pattern of progesterone profile was recorded by Williams and Sharp [10] in WLH hens. Below this or around this age the ovary is expected to have the large number of follicles below 10 mm in size, which secretes the large quantity of estrogen from theca layer. After 18th wks of age, follicles mature continuously and they grow from less than 1 mm to approximately 35–40 mm in diameter.

They are recruited in to the yolk-filled hierarchy when they have reached approximately 10 mm or above in size. Before recruitment of follicles in the yolk filled hierarchy (below 10 mm size of follicles or around 18 wks of age), they produce large quantities of various hormones such as dehydro epiandrosterone, androstenedione, and estrogen. After recruitment of follicles in the yolk-filled hierarchy, they produce decreasing quantities of estrogens and gain the capacity to produce progesterone. After progressing through the yolk-filled hierarchy with advancement of age, the largest ovarian follicular loses the ability to produce androgens and estrogens and secretes the large quantities of progesterone in the systemic circulation [11]. This might be the possible reason in our study, which causes the drastic reduction in estrogen level after 18 wks in WLH hens and simultaneously significant ($P < .05$) increase in the level of progesterone in blood circulation (Tables 1–5).

The sexual maturity in desi fowl occurred late as evidenced by peak of estrogen level exhibited nearly 6 wk later (24 wk) than WLH. This may be due to breed differences, which vary from breed to breed. After 24 wks, the reduction of estrogen concentration is associated with increase in the level of progesterone (Tables 4 and 5). This preovulatory surge of progesterone stimulates the release of LH, which in turn causes ovulation of the largest follicle. Besides ovulation, LH stimulates steroidogenesis in ovary and causes the production of androgens and estrogens that stimulate reddening of comb, deposition of medullary bone, formation of oviduct, and production of the yolk precursors by the liver [11–13]. Within the desi fowl, at all intervals, the hormonal profile of both the hormones was found higher in KN than AP. This may be related with early sexual maturity (2–3 wk) in KN.

The concentration of T3 hormone was also noticed maximum in early ages (6–12 wks). Thereafter, a linear and significant ($P < .05$) decrease was recorded till the end of experiment (30 wks) in all the breeds. These results indicated that T3 hormones expressed prominent role in growth and development of birds as evidenced by significant reduction of its concentration with age as compared to T4 hormone. It is well known that T3 plays a far greater role in bio-oxidation process in cells than does T4 [14]. Almost

identical effects of T3 and T4 in birds were observed by Shellbarger [15], which is not the case in mammals. Bobek et al. [14] later investigated that T3 is the main thyroid hormones regulating oxygen consumption particularly in young chickens. Klandorf et al. [16], finally confirmed that T3 in chickens is a metabolically more active substance than T4. Thyroxine constitutes approximately 60% and T3 approximately 40% of the circulating thyroid hormone in the domestic birds [17]. Nevertheless, the higher profile of both hormones during early 6 wks of age may be reflected to an increased metabolic rate, especially to energy production as well as to their involvement in the growth and development of the chickens at early age of life.

It is well documented that thyroid hormone T3 and T4 are involved in wide range of metabolic activities influencing the growth and development of birds. The thyroid hormones are primarily involved in energy production by increasing the metabolic rate in turn heat production. The importance of these T3 and T4 hormones to the growth and development of organism is most visible in deficient animals that exhibit stunted growth and lower productivity. Since the production of broilers in poultry industry lasts only 6 wks, now one would expect that how important are the T3 and T4 in the growth and development of chicken [18].

To compare the age-dependent variation in the mean values of T3 and T4 in different breeds of chicken, we do not have data in the literature to compare with others. However, Stojević et al. [18], reported the age-dependent (3 to 6 wk) increase in the concentration of T3 and T4 hormone. As available literature is more scarce, therefore, this study suggested conducting more planned investigations on T3 and T4 hormone in view of their importance in poultry production.

4.2. Phosphatases and Transaminases Activities. The ALP activity in blood commonly used as an aid to the diagnosis of bone diseases and obstructive jaundice. In poultry, the main objective for the study of this enzyme was to find out the possible relationship between enzyme activity and various economic traits [19–22]. In our study, the activity of ALP decreased significantly ($P < .05$) with the increase of age from 6 to 24 wks. The increase of age is associated with

economic traits (egg production), where the activity of ALP decreased as evidenced by the results presented in Tables 1–5. This variation in enzyme activities may be due to breed differences, which reflect variation in the overall metabolic rate in different breeds. This indicated that ALP activity is negatively correlated with economic traits. These results find the support from the work carried out by A. Mazumder and N. Mazumder [23] in WLH breed in which the activity of ALP decreased from 62.85 K.A. units (12 wks) to 25.80 K.A. units (24 wks) with the advancement of the age. The present finding is also in agreement with other workers [20, 24]. In contrast, several workers reported that higher ALP activity is associated with higher productivity [25]. Foregoing discussion on the possible association between ALP activity and various economic traits in poultry revealed that the findings are contradictory indicating more investigations are needed. These results suggested that the activity of GOT and GPT is positively correlated with age. This correlation of these enzyme systems with age in the body might be as per the requirement of development of various biological systems in the body including reproductive system. On both the GOT and GPT enzymes in fowl, we do not have data for comparison with others.

5. Conclusion

From the ongoing discussion, it may be concluded that sexual maturity of the Indian native desi fowl occurred nearly 6 wk later (24 wk) than WLH (18 wk).
