Tinea corporis

Abstract Fungal infections by dermatophytes can present with unusual clinical manifestations, which can cause diagnostic difficulties. The authors present the case of a patient with cutaneous infection by *Nannizia gypsea*, initially treated erroneously with topical corticosteroids due to a wrong diagnosis. It was cured after antifungal treatment.

The authors describe the case of a 43-year-old male patient, resident in Jacarepaguá, Rio de Janeiro, Brazil who, at dermatological examination, presented a discreetly pruriginous erythematous plaque, showing a nummular aspect, with peripheral pustules and tonsured hair, located on the right forearm. A similar adjacent lesion was observed; the patient indicated that their onset occurred after he returned from a farm in the countryside area of Rio de Janeiro (Fig. 1).

He underwent oral treatment with cephalixin and topically with corticosteroids, without improvement. As diagnostic hypotheses, sporotrichosis and pyoderma were suggested. The biopsy of a skin fragment stained with H & E showed an enlarged hair follicle containing hyaline hyphae in its distal portion (Fig. 2), which are also evident in the silver impregnation by Grocott's method (Fig. 3), and PAS staining. There was also an inflammatory reaction in the superficial dermis, with a predominance of mononuclear cells. The culture for common germs was negative. *Nannizzia gypsea* was isolated from the skin fragment on Mycosel agar, confirming the diagnosis of tinea corporis. He underwent treatment with cyclopyroxolamine spray, which led to cure after 30 days (Fig. 4).

The prevalence of dermatophytoses caused by *Nannizia gypsea* ranges from 0.72% to 0.5%.^{1,2} It is possible that the low prevalence is due to the exuberant inflammatory

reaction, as this is a geophilic fungus, not adapted to human parasitism.^{3,4} In general, the clinical presentation of tinea corporis is quite characteristic, presenting a mild or moderate inflammatory reaction, sometimes vesicular or

vesicular-crusted, on the edge of a macular, erythematous squamous lesion.⁵ In this case, the clinical presentation of the lesion was not typical of dermatophytosis of the body; on the contrary, it was a plaque with pustules. In Rio de Janeiro, due to the hyperendemicity of sporotrichosis, this was, naturally, the first hypothesis. Currently, in the state of Rio de Janeiro, lesions that have an infiltrated aspect, without flaking, and that do not initially respond to systemic antibiotic therapy are suggestive of sporotrichosis.

Cases of dermatophytosis with atypical clinical presentation, as reported, may be mistakenly treated with ineffective or inadequate medications, if there are no specific complementary tests. Corticosteroids and antibiotics are the most common drugs used.⁶

In most cases, topical treatment with terbinafine, butenafine, cyclopyroxolamine, or azoles for two to four weeks is simple, cost-effective, and sufficient for healing.^{7,8} Systemic treatment with oral antifungals, such as terbinafine and itraconazole, should be considered in immunosup-

pressed patients, in extensive and/or recurrent lesions, or in those who do not respond to the use of topical medications.

With the report of this case, the authors aimed to reinforce the idea that complementing the clinical diagnosis with specific laboratory tests that exclude or confirm the initial hypothetical clinical diagnoses can avoid unnecessary and costly treatments, which often prolong the suffering of patients.
