Organocatalytic activation of isocyanides: N-heterocyclic carbene-catalyzed enaminone synthesis from ketones†

Jungwon Kim and Soon Hyeok Hong*

The first example of the use of an N-heterocyclic carbene (NHC) as an organocatalyst for the activation of isocyanides was demonstrated. On the basis of previous reports on the interaction between NHCs and isocyanides, we developed a catalytic cycle involving transient imidoyl intermediate. The reaction of ketones with isocyanides produced the corresponding enaminones with high efficiency. Control experiments suggested a novel role for the carbene in the activation of isocyanides, and a proton transfer process was found to be crucial for the generation of two activated species in the catalytic cycle. Various enaminones, some of which are not easily accessible by other methods, were synthesized in excellent yields. This study clearly demonstrates the potential of the nucleophilic activation of isocyanides in the expansion of their reactivity scope.

Introduction

Isocyanides are useful building blocks for the synthesis of various acyclic and cyclic compounds.¹ Because the terminal carbon of isocyanide can act as both a nucleophile and the carbene center, control of its reactivity is key to developing novel transformations. In many cases, the isocyanide group can act as a mild nucleophile, meaning that it undergoes electrophilic activation in the presence of an electrophilic compound. In addition, various metal-based catalysts allow further transformations after the incorporation of the isocyanide motif into the starting substrate. Pd-catalyzed insertion reactions,² Cu(Ag)-mediated electrophilic activation,³ and Cu-alkoxide systems⁴ for the generation of formimidate intermediates are well developed isocyanide activation strategies (Scheme 1A). Because of the mild nucleophilicity of the carbon atom of the isocyanide group, its utilization as a nucleophile has been limited to the use of highly electrophilic reaction partners, such as carbonyl compounds and metal catalysts. This has been a critical hurdle for achieving metal-free, non-Ugi-type transformations. In order to overcome this shortcoming, we envisioned a new approach where the isocyanide group is activated by a 'nucleophilic moiety' to transform the isocyanide into a highly basic intermediate. The reactions of isocyanides with external

nucleophiles are relatively rare and most of them require highly reactive organometallic nucleophiles (Scheme 1B).⁵ The incorporation of milder nucleophiles into the isocyanide is possible only in the presence of an electrophilic group near the reactive center to trigger intramolecular cyclization reactions

(Scheme 1B).⁶ To the best of our knowledge, the catalytic nucleophilic activation of isocyanides has not yet been reported.

We chose N-heterocyclic carbenes (NHCs) as potential nucleophilic activators.⁷ There have been several reports on the formation of ketenimines from the reaction between carbenes and isocyanides,⁸ such as diamidocarbene (DAC),^{8c,8d} cyclic (alkyl)(amino)carbene (CAAC),^{8e} and acyclic di(amino)carbene (ADAC)^{8e} (Scheme 1C). Among them, a computational study on the formation of an imidoyl intermediate from the reaction between an imidazole-based NHC and an isocyanide, which proposed a zwitterionic imidoyl adduct as a favorable structure, attracted our attention (Scheme 1C).^{8c,8e} Although this intermediate was not stable enough to be isolated, the transient zwitterionic imidoyl intermediate containing a localized anion charge on the terminal carbon of the isocyanide structure could be highly reactive.^{8e} On the basis of this report, we envisioned the possibility to enhance the nucleophilicity (basicity) of the terminal carbon atom of the isocyanide group by conversion into an imidoyl intermediate (Scheme 1D). This intermediate would abstract a proton from an unactivated substrate, generating activated nucleophilic and electrophilic species. Thus, formal X-H insertion without the aid of a metal catalyst could be achieved. To realize this strategy, we first attempted the reaction between isocyanide and ketone derivatives, which can form an enaminone as the final product (Scheme 1E). The proposed methodology provides an unprecedented synthetic route to enaminones *via* C–C bond formation. Although various synthetic strategies have been developed for the preparation of enaminones,⁹ the limited scope and relatively low availability of reagents are significant drawbacks to these procedures. Herein, we report a novel organocatalytic enaminone synthesis from isocyanides and ketones with excellent functional group tolerance. This methodology is applicable to the preparation of a wide range of enaminones *via* the first catalytic activation of isocyanides by an NHC.

Results and discussion

At the outset, the reaction between acetophenone (**1a**) and 4-methylphenyl isocyanide (**2a**) was conducted, and in our first attempt the desired (*Z*)-enaminone (**3a**) was isolated in 19% yield (Scheme S1†). The exclusive (*Z*)-selectivity of **3a** can be explained by intramolecular hydrogen bonding, which was confirmed by ¹H NMR spectroscopy.¹⁰ To further increase the reactivity, several reaction parameters were varied (Tables 1 and S1–S4†). Among the several solvents examined, DMA afforded the highest yields of **3aa** (entries 1–4). Next, various bases were evaluated, showing that replacing a strong base (NaOtBu) with a relatively weak one (K₂CO₃) did not significantly affect the reactivity (entry 5 and Table S1†). Interestingly, the use of IMes as an organocatalyst was critical to obtain the desired product, and the reaction did not proceed at all in the presence of other related imidazolium salts (entries 6 and 7, Table S3†). Screening of the amount of NHC salt, base, and solvent and increasing the reaction temperature resulted in further enhancement of the reaction efficiency (entries 8–10). The reaction time could be reduced to 6 h without significant decrease in reactivity

(entry 11). The reaction without NHC salt did not generate the desired product (entry 12) or showed lower reactivity (entry 13), proving that this transformation cannot be catalyzed only by a base.

With the optimized conditions in hand, the scope of the reaction was investigated. Firstly, the reactions of various methyl ketones were performed (Table 2). *para*-Substituted acetophenones produced the corresponding enaminones in good to excellent yields (**3aa–3ea**). In particular, halide-containing substrates were tolerated under the reaction conditions demonstrating the advantage of this organocatalytic approach (**3ca** and **3da**). *ortho*-Substituted acetophenones also gave excellent yields within 6 h (**3fa** and **3ga**), and bis-substituted acetophenone **1h** produced the corresponding (*Z*)-enaminone **3ha** in 75% yield. In addition, heteroaromatic methyl ketones exhibited excellent reactivity (**3ia–3ma**). Non-aromatic methyl ketones could also be used in the reaction, albeit lower yields were obtained (**3na** and **3oa**).

Next, we turned our attention toward the synthesis of trisubstituted enaminones. The synthesis of α -alkyl enaminones has been sparsely reported using specifically prepared starting materials,¹¹ such as triazolyl alkanols,^{11a,11b} β -dicarbonyl compounds,^{11c,11d} and α,β -unsaturated carbonyl compounds.^{11e} To our delight, our strategy could provide an alternative approach starting from readily available ketones (Table 3). Ring-fused acetophenone derivatives efficiently produced the corresponding trisubstituted (*Z*)-enaminones under the optimized conditions (**3pa–3ra**). In the case of propiophenone and other α -alkyl-substituted acetophenones, stoichiometric amounts of NaOtBu were used to facilitate enolate formation and protonation of the imidoyl intermediate by *in situ* generated *t*BuOH. Under these modified reaction conditions, α -substituted ketones with a linear alkyl chain or a branched alkyl group were all reactive, affording α -alkyl (*E*)-enaminones in good to excellent yields (**3sa–3xa**). The exclusive (*E*)-selectivity can be rationalized by the steric repulsion between the phenyl group and the α -alkyl substituent, as previously reported,¹² and the (*E*)-configuration of **3sa** was further determined by X-ray crystallography (see ESI†).

The reaction of various isocyanides was evaluated (Table 4). Phenyl isocyanide (**2b**) and *p*-methoxyphenyl isocyanide (**2c**) exhibited good to excellent reactivity. However, halogen-substituted isocyanides gave only moderate yields under several reaction conditions (**3ad** and **3ae**). *ortho*-Substituted isocyanides (**3af** and **3ai**), 4-styryl isocyanide (**3ag**), and disubstituted isocyanide (**3ah**) were all tolerated under the reaction conditions, with moderate to good reactivity. Biphenyl isocyanide (**2i**) and naphthyl isocyanide (**2j**) afforded the corresponding (*Z*)-enaminones in good yields (**3ai** and **3aj**). Unfortunately, alkyl isocyanides were not reactive, presumably because the relatively low electrophilicity of the terminal carbon atom of the alkyl isocyanides prevents the nucleophilic attack of the NHC catalyst.

Encouraged by the high efficiency of the developed reaction, we further evaluated the scope of the carbon nucleophiles (Scheme 2). When bis-acetyl compounds (**1y** and **1z**) were treated with excess amounts of **2a**, formation of bis-(*Z*)-

Scheme 2 Expansion of the scope of carbon nucleophiles and gram-scale synthesis.

In order to gain mechanistic insight into this transformation, control experiments were conducted (Scheme 3). When the standard reaction was performed with free carbene (IMes), a comparable yield of the desired product was obtained, suggesting that free carbene is involved in the catalytic cycle (Scheme 3A). To further reveal the role of the NHC catalyst, ethyl *N*-phenylformimidate (**2b'**), which can be considered as an analogue of the imine–azolium intermediate, was treated with **1a** (Scheme 3B). Even in the presence of stoichiometric amounts of IMes, the reaction yield was not improved, suggesting that the major role of NHC is not ketone deprotonation. In contrast, the use of stoichiometric amounts of a strong base led to full conversion of the ketone to enaminone. This was further supported by the direct alkylation reaction *via* a stepwise approach with acetophenone and benzyl bromide (Scheme 3C). When

Scheme 3 Control experiments.

a stoichiometric amount of KOtBu was used in the deprotonation step, enolate **1a'** was observed and α -benzylated product **4** was produced, whereas the use of IMes as a base was not effective for the same transformation. Even at an elevated temperature of 60 °C in THF, we could not observe **1a'** with IMes. From these observations,¹⁴ together with the literature data for the p*K*_a values of acetophenone and related NHC salt,¹⁵ we concluded that the major role of the NHC catalyst is to activate the terminal carbon atom of the isocyanide, generating a more basic imidoyl intermediate, which deprotonates the ketone. Besides, we performed a stoichiometric reaction between an independently generated enolate **1a'** and isocyanide **2a** to check the possibility of the direct addition of **1a'** to isocyanide. **3aa** was obtained in a decreased isolated yield than that of the original catalytic conditions (55% vs. 86%), suggesting that a minor pathway of direct addition of enolate to isocyanide could exist (Scheme 3D). Considering the use of a stoichiometric amount of enolate anions for the reaction under an excess amount of isocyanide as the sole coupling partner, such direct addition process between isocyanide and enolate would not be the major pathway in our reaction.

Based on the control experiments and earlier literature, a catalytic cycle is proposed in Scheme 4. The reaction of IMes with isocyanide generates an imidoyl intermediate (**Int A**), which can perform deprotonation to afford an imine–azolium intermediate (**Int B**). During this step, the proton source can be either the ketone, which directly produces the corresponding enolate (Path A), or unreacted imidazolium salt/protonated base (Path B). Trials for the observation of **Int A** or **Int B** through stepwise nucleophilic attack and protonation *via* ¹H NMR

Scheme 4 Proposed catalytic cycle.

spectroscopy were conducted, but promising species were not detectable.¹⁶ We reasoned that those intermediates derived from IMes are transient species in catalytic conditions, which structures are relatively different from that of the stable ketenimine adduct. However, the instability of the intermediates would be a driving force to achieve overall turnover of the catalytic cycle in the reaction mixture. Deprotonation of the ketone by the regenerated base, *i.e.*, Path B, is dominant when Path A is disfavored by steric repulsion interactions such as in the case of bulky ketones. These steps lead to the formation of activated nucleophiles (enolate) and electrophiles (**Int B**). Subsequent coupling and isomerization reactions produce the desired enaminone, with regeneration of IMes. Direct coupling between the generated enolate and isocyanide could be also possible, although it would be a minor pathway in the catalytic cycle.

Conclusion

In conclusion, we demonstrated the first NHC-catalyzed C–C bond formation reaction between ketones and isocyanides. Using an imidazolium-based NHC catalyst, diverse enaminones were synthesized in excellent yields. We believe that the major role of the NHC in the catalytic cycle is to transform the isocyanide moiety into an imidoyl intermediate, followed by the formation of a highly electrophilic imine–azolium intermediate *via* a proton transfer process. The *in situ* generated enolate attacks the terminal carbon atom of the isocyanide to complete the catalytic cycle. In this strategy, isocyanides are used as new substrates for NHC organocatalysis. Detailed mechanistic studies and further applications of the developed strategy are in progress.

Am. Chem. Soc.*, 2004, **126**, 8717.
- 16 Reactions between stoichiometric amount of IMes and **2a** were monitored by ¹H NMR in benzene-d₆ and THF-d₈ respectively, but unidentifiable broadened peaks were observed in both cases. We think that generated imidoyl intermediate could initiate oligomerization process, because fast conversion of **2a** was observed. In the developed reaction, an appropriate pronucleophile, ketone in our reaction, could intercept reactive imidoyl intermediate and prevent the unwanted side reactions.
