Bone formation, in skeletal development or in osseointegration processes, is the result of interaction between angiogenesis and osteogenesis. To establish osseointegration, cells must attach to the implant in a direct way without any deposition of soft tissue. Structural design and surface topography of dental implants enhance the cell attachment and can affect the biological response. The aim of the study was to evaluate the cytocompatibility, osteogenic and angiogenic markers involved in bone differentiation of human periodontal ligament stem cells (hPDLSCs) on different titanium disks surfaces. The hPDLSCs were cultured on pure titanium surfaces modified with two different procedures, sandblasted (Control—CTRL) and sandblasted/etched (Test—TEST) as experimental titanium surfaces. After 1 and 8 weeks of culture VEGF, VEGF-R, and RUNX2 expression was evaluated under confocal laser scanning microscopy. To confirm the obtained data, RT-PCR and WB analyses were performed in order to evaluate the best implant surface performance. TEST surfaces compared to CTRL titanium surfaces enhanced cell adhesion and increased VEGF and RUNX2 expression. Moreover, titanium TEST surfaces showed a different topographic morphology that promoted cell adhesion, proliferation, and osteogenic/angiogenic commitment. To conclude, TEST surfaces performed more efficiently than CTRL surfaces; furthermore, TEST surface results showed them to be more biocompatible, better tolerated, and appropriate for allowing hPDLSC growth and proliferation. This fact could also lead to more rapid bone–titanium integration.

Keywords: titanium disks, angiogenesis, osseointegration, mesenchymal stem cell, cytocompatibility, human periodontal ligament stem cells

INTRODUCTION

In the last few years, mesenchymal stem cells (MSCs) have been performing a primary function in regenerative medicine and tissue engineering. They offer the opportunity to restore, recover, and renovate cells, tissues, and organs (Di Nisio et al., 2015). In dentistry, human periodontal ligament stem cells (hPDLSCs) have been the mostly utilized MSCs population. They have been collected

from the periodontal ligament, a specialized connective tissue that linked alveolar bone socket with the tooth root surface, distinguished by various cell populations as osteoblasts, fibroblasts, epithelial cells, endothelial cells, and stem cells (De Colli et al., 2015; Safi et al., 2019). The hPDLSCs show multipotent and proliferative properties (Winning et al., 2017). In fact, hPDLSCs improved the interface formation among dental devices utilized for implants and bone in an event defined osseointegration (Kado et al., 2019). Devices used in dentistry are composed by materials with chemical and physical properties able to differentiate stem cells into osteoprogenitor cells (Kim et al., 2014). Titanium is one of the materials mostly used in this field. It has a good biocompatibility, is relatively inert, and is defined by surface features such as topography, roughness, and hydrophilicity that support cell growth and differentiation, influence the protein adsorption of the device implant and its immobilization (Gittens et al., 2014; Liu et al., 2017; Selders et al., 2017; Yadav et al., 2017). One of the primary aims of research in dentistry has been to improve the bone-implant interface and the titanium bioactivity by modifying its surface structure. The formation of a direct contact between the implant and mineralized bone is the result of angiogenic and osteogenic differentiation processes (Hanawa, 2019). There is no bone formation without a prior formation of newly -formed blood vessels. The existence of blood vessels shows a vital role in bone renewal processes and in implant osseointegration (Beltran-Partida et al., 2017; Genova et al., 2019; Raines et al., 2019b). The relationship between the complex molecular mechanisms of blood vessels and bone formation is still relatively unexplored, and a better understanding of these features would be welcomed. Recent studies have reported a close relationship between MSCs and endothelial cell, improving vasculogenesis (Genova et al., 2019; Raines et al., 2019b). It has been hypothesized that changes in the microstructure of implant surface could have a relationship with the secretion by osteoprogenitor cells of pro-angiogenic substances (Raines et al., 2019a). The modification of titanium implant surfaces, by chemical or physical treatment, could represent an effective method, affecting cell adhesion and differentiation (Zahran et al., 2016). In the oral cavity, numerous typologies of MSCs have been described (Rajan et al., 2016; Bianchi et al., 2017; Diomedede et al., 2018c). As extensively reported in the literature, MSCs can be easily isolated from craniofacial bones during routine dentistry procedures. Owing to their embryological origin from neural crest, they appear as a suitable cell population to evaluate cell-biomaterial connection in the craniofacial field, involving osteoinductive/osteointegrative events. The biological and immunomodulatory characteristics of MSCs could be affected by chemistry and topography of implant surfaces (Conserva et al., 2019). Until now, six different human dental stem cells have been reported in the literature: human dental pulp stem cells (DPSCs), human exfoliated deciduous teeth stem cells (SHED), hPDLSCs (Sinjari et al., 2019), human apical papilla stem cells (APSCs), human dental follicle stem cells (DFSCs), and human gingival GMSCs (Romeo et al., 2018; Trubiani et al., 2019b). In particular, MSCs taken from the human periodontal ligament can be easily isolated and manipulated to use as an *in vitro* model

to assess cell cytocompatibility of different materials (Diomedede et al., 2016; Pizzicannella et al., 2018b). Moreover, the complex restoration of the periodontal ligament has shown unexpected clinical results and preserves an attractive challenge in dentistry (Trubiani et al., 2012b; Pizzicannella et al., 2018a). The goal of the current work was to evaluate the presence of angiogenic and osteogenic markers as RUNX2 and VEGF, and their receptors, on different titanium disks surfaces.

MATERIALS AND METHODS

Ethics Statement

The protocol and informed consent from human periodontal ligament biopsies were accepted by the Medical Ethics Committee at the Medical School, “G. d’Annunzio” University, Chieti, Italy (no. 266/17.04.14). The formal consent form was subscribed by all patients prior to sample collection. The Department of Medical, Oral and Biotechnological Sciences and the Laboratory of Stem Cells and Regenerative Medicine are certified in accordance with the quality standard ISO 9001:2015 (certificate no. 32031/15/S).

Cell Culture

Five human periodontal ligament biopsies were scraped from human premolar teeth of patients in general good health conditions. The tissue was obtained by scaling the roots using Gracey’s curettes (Trubiani et al., 2012a; Diomedede et al., 2018b). The samples were washed five times with PBS (LiStarFish) and cultured using TheraPEAK™ MSCGM™ CD BulletKit serum free, chemically defined (MSCGM-CD) medium for the growth of human MSCs (Lonza, Basel, Switzerland) (Libro et al., 2016). The medium was changed twice a week, and cells migrating from the explants tissue after reaching about 80% of confluence, were trypsinized (LiStarFish), and after, were subcultured until passage 2nd (P2).

hPDLSC Characterization

The study of hPDLSC phenotype was performed by flow cytometry, as earlier stated (Diomedede et al., 2018a). Shortly, 2.5×10^5 cells were incubated for 30 min with the following antibodies: anti-CD44-FITC, anti-CD105-FITC, and anti-CD29-PE (Ansell Corporation, Bayport, MN, United States); anti-CD14-FITC (Miltenyi Biotec, Bergisch Gladbach, Germany); OCT3/4-PE, SOX2-Alexa488, CD73-PE, CD90-FITC (Becton Dickinson, San Jose, CA, United States) and CD34-PE (Beckman Coulter, Fullerton, CA, United States). After incubation with proper secondary antibodies, fixation in 1 mL of PBS 0.5% paraformaldehyde and washing, cells were detected utilizing a FACStar -plus flow cytometry system and the FlowJo™ software v10.0.7 (Tree Star, Ashland, OR, United States). The hPDLSCs at P2 were analyzed with an inverted light microscopy Leica DMIL (Leica Microsystem, Milan, Italy).

Dental Implants

In the current work, two different titanium disk surfaces, provided by Implacil De Bortoli (São Paulo, Brazil), have been

utilized: Control (CTRL) and Test (TEST). The disks were manufactured of commercially pure titanium (ASTM F67). The surface of CTRL disks was obtained by sandblasting with a mix of titanium oxide powder and then cleaning with purified water, enzymatic detergent, acetone, and alcohol, while the surface of TEST disks, after the same sandblasting procedure, was cleaned with purified water, enzymatic detergent, acetone, alcohol, and then a double acid attack with acetylic acid.

Atomic Force Microscopy (AFM)

The morphologies of two disk surfaces, CTRL and TEST, were assessed by Atomic Force Microscopy (AFM), exploiting a Multimode 8 Bruker AFM microscope (Bruker, Milan, Italy) coupled with a Nanoscope V controller (Bruker AXS, Marne La Vallee, France) and commercial silicon tips (RTESPA 300, resonance frequency of 300 kHz, and nominal elastic constant of 40 N/m) were used in ScanAsyst air mode. The ScanAsyst air mode technique was used for the AFM observations with a scan size of 10 μm . Then the Nanoscope analysis 1.8 software was adopted to analyze images and 3D reconstruction. The roughness average (Ra), that is the arithmetic mean of the absolute values of the height of the surface profile, was assumed for the statistical analysis. Five samples of each group were analyzed, and the mean values (\pm standard deviation) were considered for statistical analysis (Mastropasqua et al., 2020).

Scanning Electron Microscopy (SEM) Analysis

CTRL and TEST samples were cultured with hPDLSCs for 21 days and successively were fixed for 4 h at 4°C in 4% Glutaraldehyde in 0.05 M phosphate buffer (pH 7.4), dehydrated in growing ethanol concentrations, and then critical point dried. They were then mounted on aluminum stubs and gold coated in an Emitech K550 (Emitech Ltd., Ashford, United Kingdom) sputter coated before imaging by means of SEM (ZEISS, EVO 50) (Gugliandolo et al., 2018).

Cell Viability

The cell viability of hPDLSCs seeded with or without CTRL and TEST samples was measured by the quantitative colorimetric MTT [3-(4,5-dimethyl-2-thiazolyl)-2,5-diphenyl-2H-tetrazoliumbromide test] (Promega, Milan, Italy) as earlier described (Cavalcanti et al., 2015). Into a 96-well culture plate with MSCBM medium (Lonza), 2.5×10^5 cells/well were cultured after 24 h of incubation at 37°C, 15 μl /well of MTT was added to culture medium, and cells were incubated for 3 h at 37°C. The supernatants were read at 650-nm wavelength utilizing an ND-1000 NanoDrop Spectrophotometer (NanoDrop Technologies, Rockland, DE, United States). The MTT assay was executed in three independent experiments.

Alizarin Red S Staining (ARS)

After 1 and 8 weeks of cultures on both CTRL and TEST titanium surfaces, calcium deposition and extracellular matrix

mineralization were evaluated by ARS staining assay. This analysis was executed according to the method previously described (Pizzicannella et al., 2019a). Human PDLSCs were washed with PBS, fixed in 10% (v/v) formaldehyde (Sigma-Aldrich) for 30 min, and washed twice with a lot of dH₂O prior to the addition of 0.5% Alizarin Red S in H₂O, pH 4.0, for 1 h at room temperature. Later, cell incubation under gentle shaking was done, and cells were washed with dH₂O four times for 5 min. For dying quantification, 800 μl of 10% (v/v) acetic acid was added to each well. Cells were incubated for 30 min with shaking, and then scraped from the plate, moved into a 1.5-ml vial, and vortexed for 30 s. The obtained suspension, overlaid with 500 μl of mineral oil (Sigma-Aldrich), was heated to 85°C for 10 min, then moved to ice for 5 min, meticulously avoiding opening the tubes until fully cooled, and centrifuged at 20,000 $\times g$ for 15 min. Five hundred microliters of the supernatant was positioned into a new 1.5-ml vial, and 200 μl of 10% (v/v) ammonium hydroxide was added to neutralize the acid, ensuring a pH between 4.1 and 4.5. One hundred fifty microliters of the supernatant taken from hPDLSCs grown with CTRL and TEST titanium surfaces after 1 and 8 weeks of culture was read in triplicate at 405 nm by a spectrophotometer (Synergy HT). The osteogenic induction was assessed in three independent experiments for each experimental group, and spectrophotometer reads were normalized per cell number.

Confocal Laser Scanning Microscopy (CLSM) Analysis

Cells grown on CTRL and TEST samples were fixed for 10 min at room temperature (RT) with 4% paraformaldehyde in 0.1 M sodium phosphate buffer (PBS), pH 7.4 (Di Giulio et al., 2015; Mazzatenta et al., 2016). After washing in PBS, cultures were processed for immunofluorescence labeling. Briefly, hPDLSCs grown on titanium disks were permeabilized with 0.5% Triton X-100 in PBS, followed by blocking with 5% skimmed milk in PBS (Giacoppo et al., 2017). Primary monoclonal antibodies to anti human VEGF (Santa Cruz Biotechnology, Santa Cruz, CA, United States), VEGF-R (Santa Cruz Biotechnology), and RUNX2 (Santa Cruz Biotechnology) were utilized, continued by Alexa Fluor 488 green fluorescence-conjugated goat anti-mouse as secondary antibodies (Molecular Probes, Invitrogen, Eugene, OR, United States). Successively, samples were incubated with Alexa Fluor 594 phalloidin red fluorescence conjugate (Molecular Probe), as actin cytoskeleton marker. Nuclei were dyed with TOPRO (Molecular Probe). Samples were put facing down on glass slides and mounted with Prolong antifade (Molecular Probes) (Diomedea et al., 2018d). Staining of samples was assessed utilizing a Zeiss (Jena, Germany) LSM510 META confocal system, linked to an inverted Zeiss Axiovert 200 microscope furnished with a Plan Neofluar oil-immersion objective (40 \times /1.3 NA). Images were analyzed utilizing an argon laser beam with excitation lines at 488 nm. After 1 and 8 weeks of culture, the percentages of VEGF/VEGF-R/RUNX2-positive cells were measured, built on the 15 pictures taken casually. Experiments have been performed in triplicates.

Gene Expression

VEGF and RUNX2 mRNA expressions were assessed by real-time PCR. For this purpose, total RNA was isolated utilizing the Total RNA Purification kit (NorgenBiotek Corp., Thorold, ON, Canada) in agreement with the manufacturer’s instructions (Zara et al., 2013). The M-MLV Reverse Transcriptase reagents (Applied Biosystems) were utilized to produce cDNA. Real-time

PCR was performed with the Mastercycler ep realplex real-time PCR system (Eppendorf, Hamburg, Germany). Expression levels in cells seeded onto CTRL and TEST samples were compared. Commercially available TaqMan Gene Expression Assays (VEGF Hs00900055_m1, VEGF-R Hs00157093_m1, and RUNX2 Hs00231692_m1) and the TaqMan Universal PCR Master Mix (Applied Biosystems, Foster City, CA,

United States) were utilized in agreement with the standard protocols (Pizzicannella et al., 2019b). Beta-2 microglobulin (B2M Hs99999907_m1; Applied Biosystems, Foster City, CA, United States) was utilized for template normalization. RT-PCR was analyzed in three independent experiments; duplicate determinations were obtained for each sample.

Protein Expression

Thirty micrograms of proteins, acquired from all samples, were processed as earlier mentioned (Mammana et al., 2019). Membranes were incubated with primary antibodies rabbit

anti-VEGF (1:750; rabbit; Sigma-Aldrich, Milan, Italy), RUNX2 (1:750; rabbit; Sigma-Aldrich), and anti-beta-actin (1:750; mouse; Santa Cruz Biotechnology, Santa Cruz, CA, United States). After five washes in PBS containing 0.1% Tween-20, samples were incubated for 1 h at room temperature with peroxidase-conjugated secondary antibody anti-rabbit and anti-mouse diluted 1:2,000 in 1 \times PBS, 3% milk, 0.1% Tween (Mazzatenta et al., 2014). Protein expression was detected using the enhanced chemiluminescence detection system (ECL; Amersham Pharmacia Biotech, Milan, Italy) with photo documenter Alliance 2.7 (Uvitec, Cambridge, United Kingdom). Signals were captured

by ECL enhancing and analyzed using a UViband-1D gel analysis (Uvitec).

Data and Statistical Analysis

The Statistical Package for Social Science (SPSS, v.21.0, Inc., Chicago, IL, United States) was used for data analysis. Parametrical methods were used after having verified the existence of the required assumptions. In particular, the normality of the distribution and the equality of variances were assessed by the Shapiro–Wilk and Levene’s tests, respectively. Data were expressed as means and standard deviation of the recorded values. The differences among the levels of the factors under investigation were assessed performing three distinct two-way ANOVA tests, one for each experiment. Tukey tests were applied for pairwise comparisons. A value of $p < 0.05$ was considered statistically significant in all tests.

RESULTS

Titanium Surface Evaluation at AFM

The two titanium disks surfaces, CTRL and TEST, were analyzed by utilizing AFM. In **Figure 1**, tridimensional micrographs of the titanium surfaces are studied. From the height panel, the Nanoscope analysis 1.8 software (Bruker, Milan, Italy) is capable of analyzing roughness (Diomedea et al., 2018a). The AFM analysis have demonstrated that the TEST group was identified by

an average roughness (Ra) of 139 ± 48.1 and 39.5 ± 13.6 nm (Ra) for the CTRL (**Figure 1**). These results extracted demonstrated that the roughness for the TEST surface is much higher compared to the CTRL titanium surface.

Human PDLSC Characterization

For the purpose of evaluating the hPDLSC phenotype, flow cytometry analysis was performed on stem cells at the second passage. *Ex vivo* expanded hPDLSCs evidenced positivity for Oct3/4, Sox-2, CD29, CD44, CD73, CD90, and CD105 (**Figure 2A**). Primary cultures of hPDLSCs at second passage, observed by light microscopy, showed a spindle-shaped morphology (**Figure 2B**).

Human PDLSC Adhesion

Cell adhesion has been evaluated by SEM and CLSM techniques. SEM observations evidenced the surface morphology of two distinct, taken into consideration, surfaces, CTRL and TEST, without cells (**Figures 3A,B**). Human PDLSCs exhibited the same adhesion capability on CTRL and TEST surfaces not having any morphological variations (**Figures 3C,D**). At CLSM level, fluorescence figures of the cytoskeleton actin (phalloidin, red) and the nuclei (TOPRO, blue) of hPDLSCs seeded on the CTRL and TEST group of samples taken after 48 h of culture established the cell adhesion. The cells adhered and spread well with a spindle fibroblast-like shape on both titanium surfaces, which confirmed that the different surface treatment did not affect the adhesion capability (**Figure 4**).

Proliferation Assay of hPDLSCs Cultured on CTRL and TEST Titanium Surfaces

MTT assay was performed at 24, 48, 72 h, and 1 week on both CTRL and TEST titanium surfaces. The hPDLSCs seeded on the TEST surface showed after 24 and 48 h a slightly higher proliferation rate compared to cells seeded on the CTRL surface and control cells. Cell cultured on the CTRL and TEST surface after 72 h and 1 week of culture showed a similar proliferation rate of control cells (**Figure 5**).

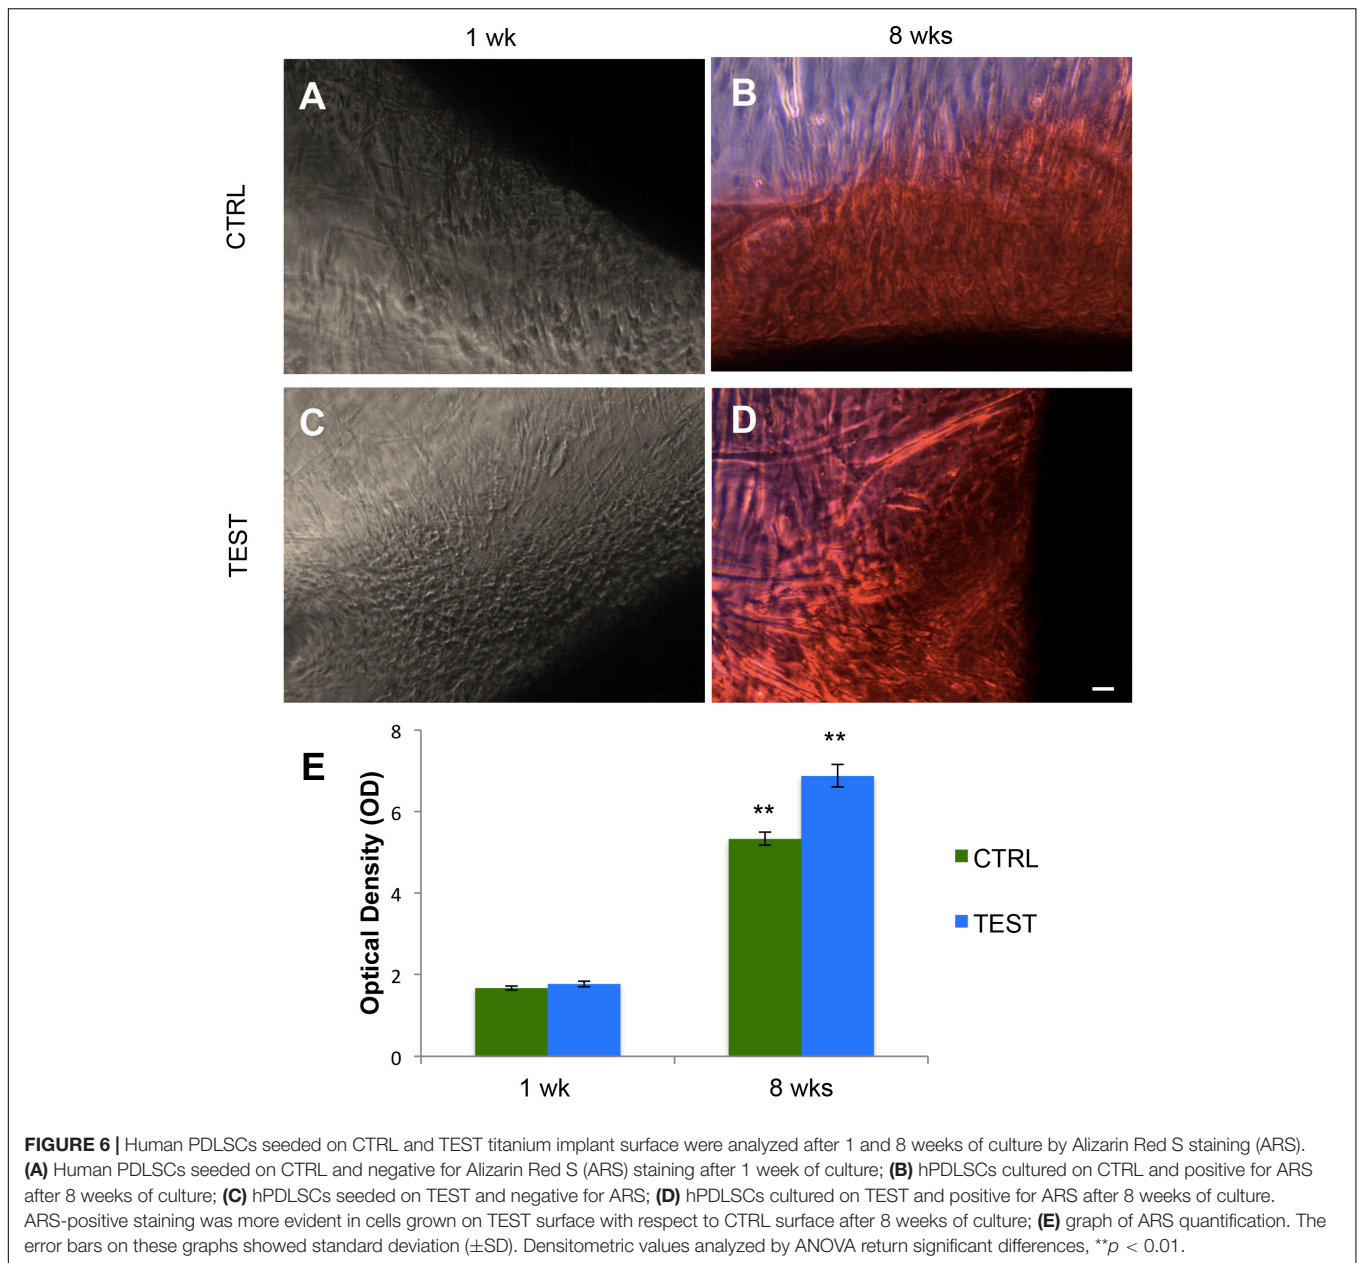

Alizarin Red S Staining of hPDLSCs Grown in the Presence of CTRL and TEST Surfaces

The osteogenic process in human PDLSCs, seeded with CTRL and TEST titanium surfaces after 1 week (**Figures 6A,C**) and after 8 weeks of culture (**Figures 6B,D**), was evaluated by Alizarin Red S (ARS) staining (**Figures 6A–D**) and its colorimetric detection (**Figure 6E**).

A significant augmented extracellular deposition was evident in cells grown after 8 weeks on the CTRL and TEST titanium surfaces compared to that of cells seeded on both surfaces after 1 week of culture (**Figure 6**).

Titanium Surfaces Influence Protein Expression at CLSM

Figures 7–10 show fluorescence images of the cytoskeleton actin (phalloidin, red) and the nuclei (TOPRO, blue) of hPDLSCs

cultured on the CTRL and TEST group of samples taken after 1 and 8 weeks of culture. The cells adhered and spread well with a spindle fibroblast-like shape on all samples, which indicates that the different surface treatment did not affect the cytocompatibility. The number of cells increased from 1 to 8 weeks (**Figures 7–10**). The CLSM observation demonstrated the tendency of osteogenic differentiation in cells cultured on TEST samples at 1 and 8 weeks of culture, which can be observed from the RUNX2-positive expression (**Figures 9, 10**). Cells seeded on TEST implant surface showed a positive expression for VEGF and VEGF-R when compared to cells cultured on CTRL samples (**Figures 7–10**). In particular, cells cultured on both surfaces after 8 weeks of culture evidenced a strong VEGF and VEGF-R expression compared to 1 week of culture.

A qualitative analysis of fluorescent photomicrographs evidenced no expression of VEGF and a slow expression of VEGF-R and RUNX2 in cells seeded on CTRL and TEST samples after 1 week. Meanwhile, cells cultured on CTRL and TEST samples after 8 weeks of culture exhibited a high positivity of VEGF, VEGF-R, and RUNX2 (**Figure 11**).

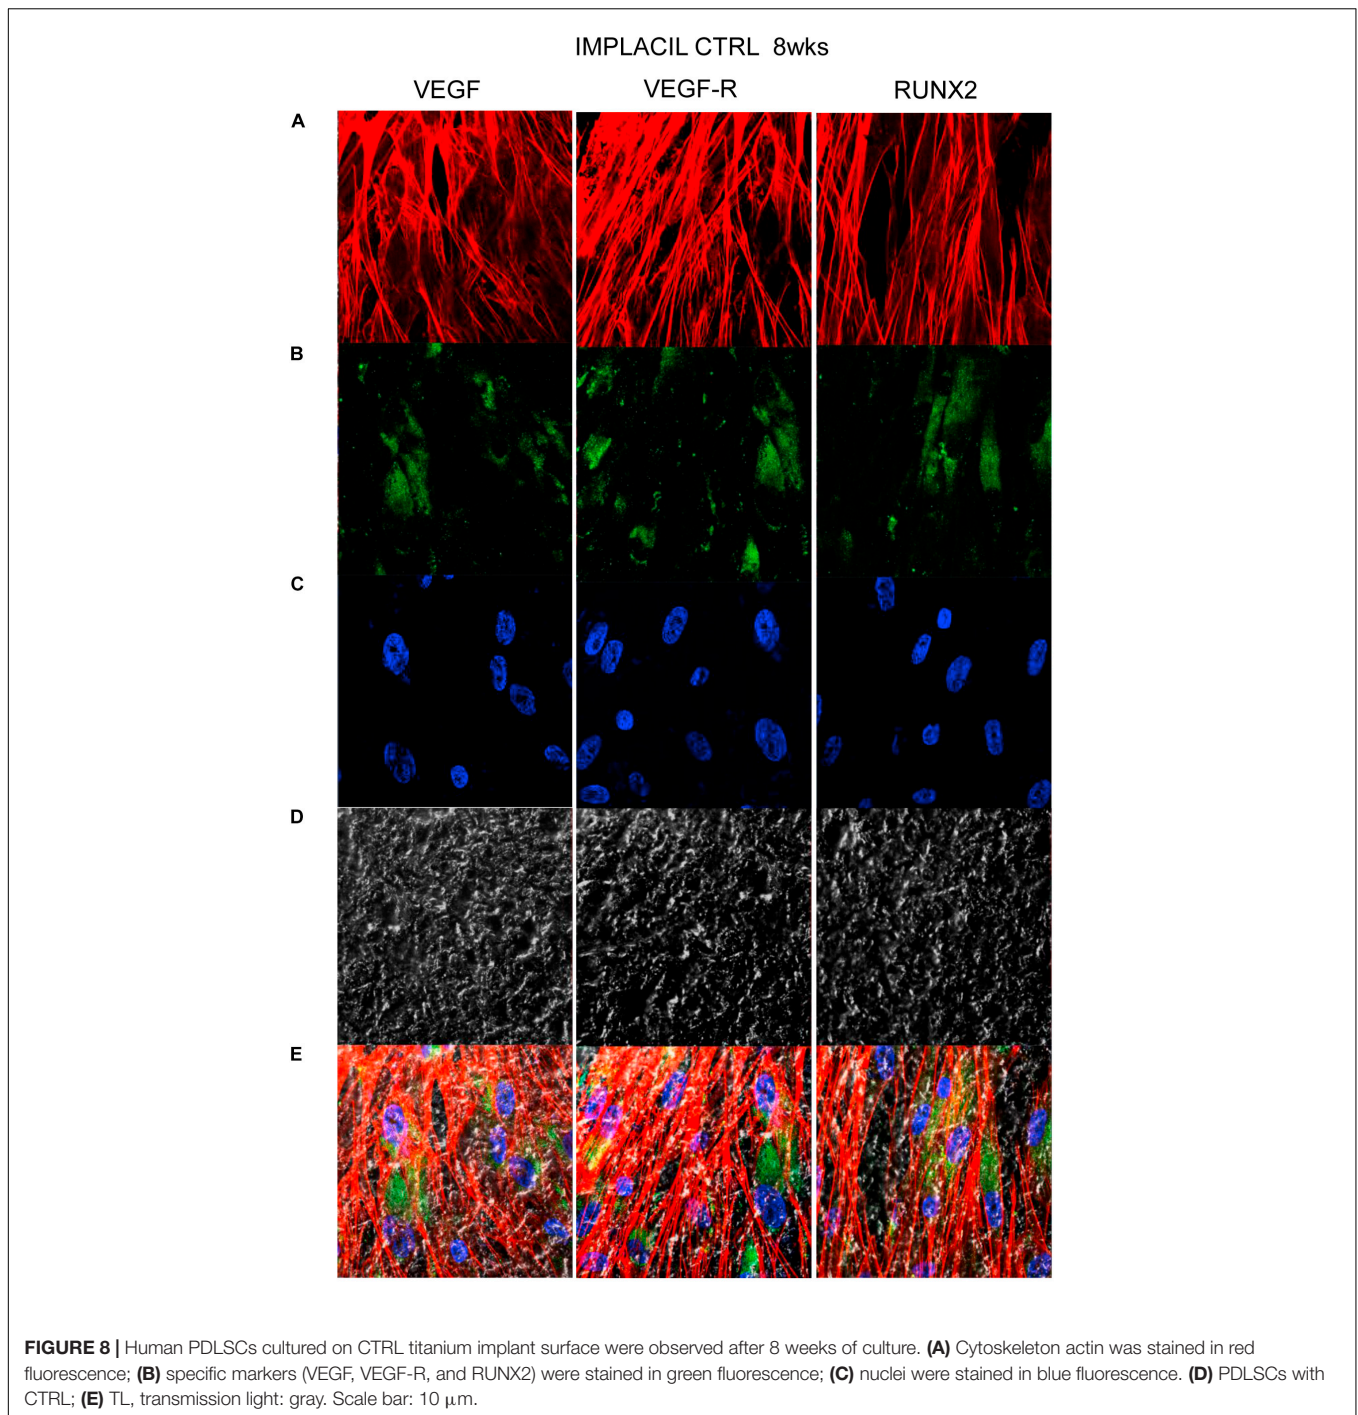

VEGF and RUNX2 Expression

Histograms evidenced the gene expression of VEGF and RUNX2 performed by RT-PCR after 8 weeks of culture (**Figure 12A**). Human PDLSCs cultured on TEST exhibited an upregulation of VEGF and RUNX2 with respect to hPDLSCs seeded on the CTRL surface. Gene expression proved the qualitative data taken by CLSM analysis.

To identify protein expression of VEGF and RUNX2 in hPDLSCs seeded on CTRL and TEST after 8 weeks of culture, a Western blot analysis was performed. Protein expression of

specific bands of VEGF and RUNX2 exhibited an over expression in hPDLSCs seeded on TEST with respect to the cells cultured on CTRL (**Figure 12B** and **Supplementary Materials**). Bar

charts of densitometric analysis evidenced the related protein band quantification (**Figure 12C**). These results confirmed the obtained gene expression data.

DISCUSSION

Recently, novel treatment techniques of titanium surfaces were suggested and tested to increment the clinical performance, and

to decrease the percentage of clinical unsuccessful attempts. The endeavors of scientific research were primarily concentrated to ameliorate the quantity and quality of bone tissue healing around implant surfaces and to increase the contact area between the implant surface and the bone tissue. All approaches were relatively surface treatments, adopted recently, driven to specific micro-structured surfaces with a better performance, linked to a greater contact area with the bone, have the capability to absorb biological molecules, induce more rapid healing, augmenting the

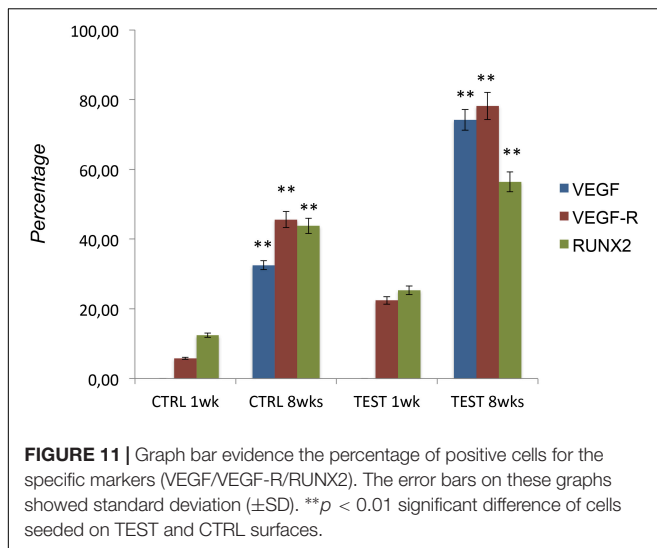

cellular reaction and long-term clinical successes. Sandblasted and acid-etched surfaces have shown good biomechanical and biological results (Zizzari et al., 2015). Chemical modifications

of titanium implant surfaces could be one active tool for achieving fast bone formation around the implant. After implant placement, several events occur between the host and the implant

surface, which consist of the primary contact of blood with the implant surface, where proteins and ligands are vigorously adsorbed onto and released from the implant surface. As widely

reported in the literature, the superficial oxide characteristics of the implant play an essential role in protein adsorption, and this fact is due to the biological tissues that cooperate

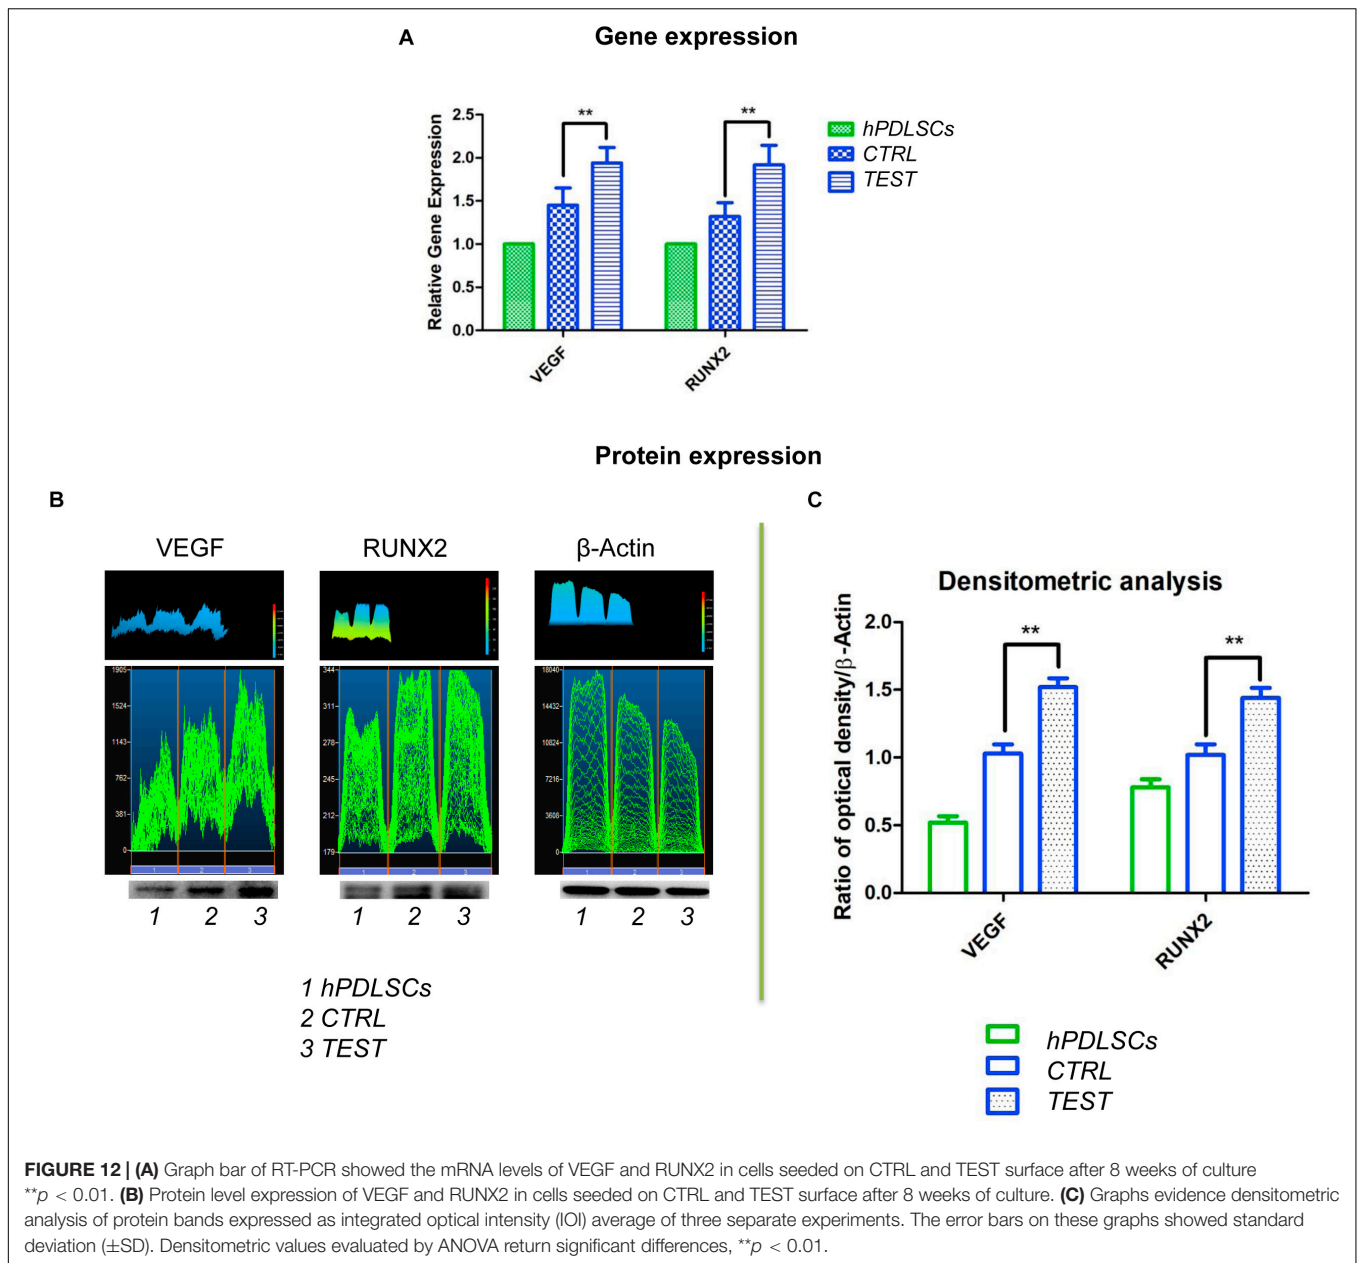

primarily with the outside atomic layers of the dental implant. Surface chemistry, topography, roughness, and wettability of the surface could influence the type, quantity, and conformation of the incorporated protein layer. Different strategies including the modification of the surface physicochemical, morphological, and/or biochemical properties have been studied in order to increase the bone-implant interface (Shah et al., 2019). The usage of MSCs appears to promote encouraging outcomes in bone tissue renewal (Trubiani et al., 2019a). MSCs, taken from the oral cavity, showed differentiation ability and immunomodulatory characteristics (Fawzy El-Sayed and Dorfer, 2016). Based on the literature, hPDLSCs are encouraging dental stem cells and are utilized as a substitute to human bone marrow mesenchymal stem cells (BMMSCs) for evaluating the osteogenic capability of titanium surfaces and for assessing osseointegration in titanium implants (Zhou et al., 2016). For this motivation, the purpose of human PDLSCs cultured with the titanium implants represents a proper and appropriate exploratory approach to deeply study the mechanisms of cell interplay with distinct implantological surfaces (Gao et al., 2015).

In the current work, the observance was focused on the *in vitro* outcomes displayed by hPDLSCs cultured on diverse titanium implant surfaces (CTRL and TEST), established with two distinct methods, in order to assess the ability of the hPDLSCs to promote angiogenesis and osteogenesis. The present results have shown that hPDLSCs cultured on both experimental titanium disks presented a similar cell proliferation rate as the control cells (Figure 5). In particular, cells seeded on the TEST surface had a better performance, in terms of proliferation rate, when compared to the CTRL surfaces, after 48 h of culture (Figure 5). No significant differences between TEST and CTRL surfaces were observed under SEM, and the hPDLSCs revealed the same adhesion capability on both surfaces without any morphological changes (Figure 3). However, hPDLSCs seeded on TEST surfaces evidenced a greater osteogenic characteristic *in vitro* with respect to the cells seeded on CTRL surfaces. In detail, hPDLSCs in culture with TEST surface had an enhanced osteogenic response with an up-regulation of RUNX2,

an early osteogenic marker. An upregulation of VEGF, VEGF-R, and RUNX2 was shown in both surfaces, after 8 weeks of culture, by Western blot (Figures 12B,C) and by CLSM analysis (Figures 8, 10). The protein expression of specific bands of VEGF and RUNX2 exhibited an over expression in hPDLSCs seeded on TEST with respect to the cells seeded on CTRL (Figures 12B,C). On the contrary, VEGF expression was not present, after 1 week of culture, on both surfaces under CLSM observations (Figures 7, 9). To further support these results, the gene expression of VEGF and RUNX2 was investigated through RT-PCR (Figure 12A). The data have shown that hPDLSCs cultured on TEST surfaces, after 8 weeks of culture, promoted an upregulation of VEGF and RUNX2 with respect to hPDLSCs cultured on CTRL surfaces (Figure 10). These results validated the data acquired by Western blot and under CLSM observations. Remarkably, a previous study evidenced that RUNX2 was a component of the genetic program that modulated the expression of VEGF throughout endochondral bone development (An et al., 2017). These data may encourage that the augmentation of RUNX2 could induce the enhanced VEGF and VEGF-R (Liu et al., 2012). The present data have shown that both titanium surfaces induced the increase of the pro-angiogenic factor VEGF, which plays an important and pivotal part in osteogenesis and bone regeneration, and particularly, the TEST surface showed a better performance with respect to the CTRL group. The relevant role of VEGF on osteogenesis has been previously established, and VEGF may regulate also calvaria ossification. Vascularization is a key process during osteogenesis and bone restoration (Lu et al., 2018). As largely reported in the literature, VEGF expression was evidenced during bone repair, indicating the key role of this angiogenic protein in bone tissue renewal. Furthermore, it was reported that VEGF administration in an experimental model of osteonecrosis of the femoral head led to bone remodeling and new bone formation (Dailiana et al., 2018; Jin et al., 2019). Blood vessels are an important component of bone formation and maintenance, and the rapid vascularization of tissue-engineered osteogenic grafts is a major obstacle in the development of regenerative medicine approaches for bone repair (Helmrich et al., 2013). The loss of VEGF in osterix-positive osteoblast progenitor cells caused a reduction in calvaria ossification, indicating that VEGF derived from these cells is required for optimal intramembranous bone formation (Duan et al., 2016). The reduction of VEGF injured endochondral bone formation, decreasing angiogenesis and osteogenesis, and causing a delay in fracture healing (Hu and Olsen, 2016).

The present results indicated that both surfaces, in contact with hPDLSCs, have shown not only osteoconductive properties, evaluated through the cell adhesion and proliferation, but also the ability to promote VEGF secretion from cells evidenced by gene expression and confocal microscopy. The induction of the release of VEGF and VEGF-R from hPDLSCs may represent an expectation for tissue engineering and, in particular, for the therapeutic growth of novel blood vessels surrounding the biomaterial in the first phase of osseointegration. In two recent studies, Raines et al. (2019a; 2019b) have shown the production of pro-angiogenic substances by osteoblasts (Raines et al., 2019a,b), while Obice et al. (2019), in an *in vivo*

human work, have established that the treatment with TiO₂ of dental abutments increased the angiogenesis levels (Obice et al., 2019). In line with the augmentation of VEGF, VEGF-R, and RUNX2 by protein and gene expression, the confocal microscopy assessments exhibited the occurrence of molecules involved in vascularization events after 8 weeks of culture in hPDLSCs cultured on TEST. This TEST samples exhibited a better performance with regard to bone restorative ability. For the first time in the current work was investigated the VEGF and its receptor expression, a key player in angiogenesis, and RUNX2, early osteogenic marker on two novel implant titanium surfaces. The novelty of the current study is related to the properties evidenced of the titanium surfaces tested. It was shown that the surface topography of the TEST surface has a

significant roughness with respect to the CTRL titanium surface. This property reported in our study is the primary fundamental and successful features on angiogenesis and osteogenesis due to augmenting the release of different pro-angiogenic growth components. Our study demonstrated that the TEST titanium surface promotes osteogenesis and angiogenesis, which has incredible prospective as a successful, engineered platform for bone tissue renewal. To conclude, these data have exhibited an essential role of the VEGF and its receptor, and a greater performance of TEST surfaces with respect to CTRL surfaces. The same data were described by Beltran-Partida et al. (2017) who found that rougher surfaces improved the endothelial proliferation (Beltran-Partida et al., 2017). This fact could be potentially useful in devising surfaces to be used in bone

restoration processes and tissue engineering and, particularly, for the therapeutic development of novel blood vessels surrounding the material in the primary phase of osseointegration. The ability to augment the levels of VEGF and its receptor may conduct to faster bone–titanium integration.

DATA AVAILABILITY STATEMENT

The datasets generated for this study are available on request to the corresponding author.

ETHICS STATEMENT

The studies involving human participants were reviewed and approved by the Medical Ethics Committee at the Medical School, “G. d’Annunzio” University, Chieti, Italy (no. 266/17.04.14). The patients/participants provided their written informed consent to participate in this study.
