

Since January 2020 Elsevier has created a COVID-19 resource centre with free information in English and Mandarin on the novel coronavirus COVID-19. The COVID-19 resource centre is hosted on Elsevier Connect, the company's public news and information website.

Elsevier hereby grants permission to make all its COVID-19-related research that is available on the COVID-19 resource centre - including this research content - immediately available in PubMed Central and other publicly funded repositories, such as the WHO COVID database with rights for unrestricted research re-use and analyses in any form or by any means with acknowledgement of the original source. These permissions are granted for free by Elsevier for as long as the COVID-19 resource centre remains active.

Osteonecrosis  
Mucormycosis  
Oral cavity lesions

## ABSTRACT

The novel coronavirus spread worldwide in 2020, causing millions of deaths and disabilities. Even though the virus was considered a respiratory virus, its adverse effects can be detected in several body systems. The article describes COVID-19 disease and its complications in the maxillofacial area. Several complications develop either in response to therapeutic modalities used to treat the underlying disease, or due to overuse of particular medications namely glucocorticoids, antirheumatic agents, interleukin 6-inhibitors, and antibiotics. This article will describe a number of complications ranging from mild complications to severe ones such as osteonecrosis of the upper jaw and facial bones, ophthalmologic and neurological complications. It will also summarize recommendations that will help prevent or minimize these complications.

## 1. Introduction

Since SARS-CoV-2 virus (severe acute respiratory syndrome virus-2) was first reported in Wuhan, China in late 2019, it has been causing successive waves of infections in different countries worldwide. Death and other serious complications were often attributed to the associated pathologies of coagulopathy, a cytokine storm, and multiorgan failure. Several co-morbidities, obesity, and old age are considered the main factors contributing to the severity of the disease [1–3].

Even though the virus belongs to the category of respiratory viruses, it can adversely affect multiple tissues and organs. Shortness of breath and respiratory complications lead to a severe acute respiratory syndrome, followed by pneumonia, and other complications including heart damage, renal failure, and gastrointestinal tract disorders [4–7]. The disease also causes severe complications in the facial area, osteomyelitis or osteonecrosis of the jaw, thrombosis of the cavernous sinuses, vision loss, neurological complications, disability, and death [8–10].

This article aims to highlight various complications caused by COVID-19 or its therapeutic modalities in the maxillofacial region.

## 2. Materials

In this analysis, articles describing the changes and complications observed in the oral cavity and facial area in the early and late stages of COVID-19 disease were searched on the Internet. We used the following data sources: PubMed, Elsevier, Google Scholar, Google search, ResearchGate, Embase, Springer, Wiley, Lancet and grey literature. The following combinations of key words were searched: COVID-19; SARS-CoV-2; new coronavirus and oral changes, jaw osteomyelitis, jaw osteonecrosis, mucormycosis. The articles found were read and analyzed according to their importance. In addition, attention was paid to the effects of drugs used in the treatment of COVID-19 as a cause of complications or a factor increasing the susceptibility to complications. Bibliography of the selected articles were also screened for the same keywords.

## 3. Results

Articles included consisted of 25 letter-to-the editor, 80 case reports, 35 clinical trials, and 39 meta-analyses published during the pandemic period.

### 3.1. Oral mucosa

Most case reports reported oral lesions that manifested in the early stages of the disease. In articles published in the early stages of the pandemic, potentially persistent conditions in the oral cavity, such as geographic tongue, and fissured tongue have been linked to Covid-19 disease. In addition, multifactorial clinical conditions in patients such as white spots on the tongue, palate, lips, numerous painful ulcers, non-specific nodules, small rashes, petechiae, geographical and cracked tongue, pustular enanthema, desquamative gingivitis, erythema were all attributed to Covid-19 without substantiation [11–18]. Scientists have analyzed the occurrence of such symptoms in the acute phase of the disease, ie in the early stages, as one of the first signs of Covid-19. This was explained by the fact that the virus enters the body through the angiotensin converting enzyme 2 (ACE 2) receptors and the abundance of these receptors in the mucous membranes of the mouth, tongue, salivary glands, as well as in the lungs, gastrointestinal tract [19–22]. Soares explained this hypothesis by an immunohistochemically method by detecting viral spike-protein in necrotic foci on the lip [23]. Some scientists have questioned this hypothesis, suggesting that changes in the oral cavity (candidiasis, ulcers) may be due to the simultaneous and continuous use of many drugs and due to their side effects. Compromised health, weakened immunity, and other systemic disorders caused by SARS-CoV-2 virus, existing saprophytes and conditionally pathogenic viruses, as well as bacteria all contribute to pathologic changes in the oral cavity during this period [24–27]. Most of these articles capture images showing changes in the oral cavity of patients, which is not enough to diagnose the condition, requiring a deeper approach to the issue.

Another notable feature was the histological and microscopic examination of a biopsy sample at the lesion site, in which inflammatory infiltrate, epithelial vacuolization, exocytosis, foci of necrosis in the intrinsic layer, and vascular thrombi were observed. It has been reported that thrombi are endothelial cells and are fibrin-based [22,28–31].

Finally, Favia et al. were able to classify oral cavity lesions based on the clinical conditions observed in 123 patients, whereby lesions of the oral mucosa are divided into 4 groups: [31].

1. Probable, pre-existing conditions, all para-physiological lesions prevalent in the general population (geographical tongue or tongue fissures).
2. SARS-CoV-2-related lesions. The author considered that the changes that occurred during the acute period of the disease, in conjunction with general symptoms, or within 1 week after the onset of general symptoms were virus-related. For example, early petechiae are a sign of vasculitis caused by SARS-CoV-2. Such changes were observed in 65% of patients.
3. Treatment-related changes. Injuries that occurred after the start of Covid-19 special therapy; For example, late petechiae or bullous angina are the results of angina-anticoagulant therapy, candidiasis-corticosteroid, and antibiotic treatment.
4. Conditions associated with poor oral hygiene. (plaque, wound-necrotic gingivitis) [31].

### 3.2. Salivary glands

There are sources in the literature that have observed acute or chronic sialoadenitis in the Covid-19 patients, and this was hypothesized to be one of the first signs of the disease. In the clinical cases reported in the articles, cases of acute parotitis/intraparotid lymphadenitis were confirmed by ultrasonography, MRI, and observed in the acute phase of coronavirus disease. This was attributed to the abundant ACE2 receptors in the salivary glands which constitute one of the organs where the virus enters. There are hypotheses that the virus, which enters the salivary gland epithelial cells through ACE2 receptors, replicates and causes lysis and inflammation [32–35]. It was noted that the presence of a certain

concentration of SARS-CoV-2 virus in the saliva allows early and easy diagnosis of Covid-19 using saliva testing [36–38].

### 3.3. Osteonecrosis/osteomyelitis

In clinical practice, serious complications and osteonecrosis osteomyelitis of the maxillofacial bones, especially osteomyelitis of the upper jaw, have been observed after COVID-19. Coagulopathies and the development of microthrombi occurring in this disease also disrupt microcirculation and the occurrence of a local ischemic state, which is likely to be the cause of the osteonecrosis of the jaw. One of the theories related to the origin of osteonecrosis is the presence of viral particles in the blood vessels, the production of large amounts of cytokines, namely interleukin-1 (IL-1), gamma interferon (IFN- $\gamma$ ), alpha tumor necrosis factor (TNF- $\alpha$ ) which cause lymphocytic vasculitis, whereas T helpers, and T-killer cells induce B cell migration, resulting in increased degradation processes [39]. The development of osteonecrosis can be also induced by certain drugs. Few studies were in the form of clinical, cohort, randomized trials that described such a complication observed during a pandemic [40].

There are analytical articles and letters to the publisher that some drugs used in the treatment of COVID-19 may cause osteonecrosis of the bones. According to them, bisphosphonates, chemotherapeutic drugs, immune drugs, as well as long-term rheumatic drugs used in the treatment and rehabilitation of SARS-CoV-2, interleukin-6 inhibitors, corticosteroids also increase the risk of upper jaw osteomyelitis or osteonecrosis [65–67].

Medication-related osteonecrosis of the jaw (MRONJ) - the exact etiopathogenesis of which is unknown, is more common in Asian peoples than in the United States or Europe. Jawbones are more sensitive to drugs than other bones. This can be attributed to the high (adverse) effects of drugs due to the remodeling of the facial-jaw area (especially alveolar growth and periodontium) due to high vascularity, metabolic rate, and constant mechanical impact. The development of jaw osteomyelitis occurs due to inhibition of angiogenesis, reduction of innate or acquired immunity, persistent micro-trauma, inflammatory or existing effects of infectious processes [69].

Because osteonecrosis of the jaw is a very severe, untreatable process that lasts for years, special attention must be paid to the factors contributing to its etiology. Histologically, MRONJ appears similar to osteomyelitis, and it is not clear whether infection is the cause or consequence of bone exposure. Interleukin-6 mediates a wide spectrum of biological activities including activation of T cells, differentiation of B cells, induction of acute phase reactants, proliferation of fibroblasts, and damage to cartilage and joints [68]. The drugs tocilizumab and sarilumab recommended by WHO for the treatment of Covid-19 have been scientifically proven to reduce the risk of death. Tocilizumab is a widely used drug primarily in the treatment of rheumatoid arthritis and retains human monoclonal antibodies that inhibit interleukin-6 (IL-6R) receptor signal transmission. However, restoration of T-lymphocyte numbers due to the blockade by these drugs of IL-6 in COVID-19 and that they cause osteonecrosis, requires further investigation. It has been noted that denosumab of the same composition causes MRONJ, and the presence of pathogenic infection in the oral cavity (periodontitis, periodontal disease) in dental patients, even in minor operations (tooth extraction), increases the risk of complications by several times [70–73].

Leflunomide (Arava) -modified antirheumatic drug has been used for many years, often with bisphosphonates and methotrexate. Studies have shown that induced RANK-L blocks the differentiation of osteoclasts and inhibits tyrosine kinases. This drug, like the above mentioned immunosuppressants, increases the risk of MRONJ during bone modulation and antiangiogenic therapy. Specifically, as a result of taking alendronic acid for 2 years and leflunomide for 6 years, 102 patients examined in clinical practice were reported to have been diagnosed with bilateral osteonecrosis of the maxilla after tooth extraction. In two more case reports, spontaneous necrosis of alveolar processes was observed when

methotrexate was used. Lymphoproliferative disorders have been reported in osteonecrosis associated with methotrexate. In addition, there are some other anti-angiogenic drugs - bevacizumab, aflibercept, sunitinib, temsirolimus, and everolimus - that have been reported to cause osteonecrosis of the jaw [73–75]. There is also evidence in the literature that the bisphosphonate group and other drugs commonly used in the treatment of tumors and osteoporosis cause osteonecrosis [76–79]. It has been suggested that in such cases, adverse oral conditions, minor surgery, or trauma may contribute to the development of the disease on the background of bone changes caused by drugs [80–82].

Although treatment of rheumatic and autoimmune complications in patients who had Covid-19 is important for maintaining their health, the risk of osteonecrosis of the maxillofacial bone must be considered when choosing drugs. Elimination of autoimmune condition such as long-term elevation of C-reactive protein, interleukin-6, and rheumatoid factor in patients with Covid-19, normalization of blood values, and recovery of the patient's condition is certainly primary, but GPs and rheumatologists are advised to choose drugs that have fewer side-effects. MRONJ is a very serious complication and difficult to treat. Given that the facial jaw area is close to the brain, the probability as a cause of death and disability in patients is very high [83–85].

Another group of drugs that are widely used in the treatment of Covid-19 is corticosteroids. Dexamethasone, and prednisolone are consistently recommended in countries around the world to stabilize the condition of patients not only in the acute phase of ARDS and pneumonia but also during the rehabilitation period. Sources report that glucocorticoids (GCS) reduce the negative effects of inflammatory mediators during cytokine storms, leading to improved pulmonary ventilation, reducing the risk of death [86,87].

GCS initially weaken the immune response and reduce capillary dilation and exudation, leukocyte infiltration, and phagocytosis. Also, they inhibit the proliferation of fibroblasts in the advanced stages. The nuclear transcription factor binds to kB (NF-kB) receptors and reduces the secretion of inflammatory mediators (cytokines, chemokines, cell adhesion molecules, inflammatory enzymes) and their receptor blockade. At the same time, it was suggested that, due to several side effects, such as hyperglycemia, hypokalemia, hypocalcemia, immunosuppression, there may be a risk of developing various infections and prolonging the treatment period [88].

In his analytical article, Dalto combined 13 articles on the development of osteonecrosis as a result of treatment of COVID-19 with glucocorticosteroids and noted and explained that glucocorticosteroids cause avascular necrosis, psychosis, and adrenal dysfunction. Studies in animals and humans have shown that GCS inhibits the maturation of osteoblasts and leads to apoptosis. Stimulation of macrophage colony-stimulating factor (M-CSF) binds to an activator of the nuclear factor-kappa B receptor (RANKL) in osteoblasts and stromal cells and decreases the production of osteoprotegerin, which in turn leads to a decrease in osteoblast function and the activation of osteoclastogenesis. Glucocorticosteroids inhibit hydroxysteroid dehydrogenase type 2 (HSD2, an enzyme that inactivates GCs) and affect osteoblast stagnation, number, and bone formation due to prednisolone. In addition to the production of sex hormones, bone morphogenetic protein, insulin growth factor, and osteocalcin secretion are also reduced, which also hurts intestinal absorption of calcium [89–91].

In addition, high doses of corticosteroids increase Willebrand factor levels in plasma. Willebrand factor (vWF) is produced and stored in endothelial cells, so an increase in its concentration means endothelial cell damage. Vascular glucocorticosteroid injuries induce platelet adhesion and aggregation, leading to thrombosis and avascular necrosis. Hormone treatment of Covid-19 has been shown to increase the risk of developing avascular necrosis as it exacerbates coagulopathy. Shetty noted that minor injuries in such patients, particularly tooth extraction, may contribute to the development of osteonecrosis [92–94]. Mehta noted that corticosteroids should be used only in refractory septic shock and acute respiratory distress syndrome due to decreased renal function

and induction of avascular necrosis [95]. Yang, Tang, Zhang, and other Chinese scientists have repeatedly stated that this group of drugs causes osteonecrosis and have recommended that treatment should be monitored for calcium intake, vitamin D and MRI, MSCT if necessary [96–98]. In addition, Yong Xiong et al. stated that glucocorticoids reduce the response of antibodies to viral clearance, causing osteoporosis and avascular necrosis [99]. Law et al. explained that pelvic necrosis develops due to high doses of these drugs [100]. Literature sources have reported that patients treated for Covid-19 have developed osteomyelitis or osteonecrosis of other bones (foot, palm, umbilical cord) under the influence of steroids and other factors [100–107].

#### 3.4. Vascular, thrombotic and neurological complications

Boymuradov et al. described the clinical course of coronavirus complications in 52 patients with osteomyelitis of the jaw, neurological symptoms (trigeminal nerve paresthesia, facial nerve paresis, headache), unilateral chronic hemisinusitis, and orbital fissure syndrome. The authors found that despite the complex treatment, the inflammatory process was very slow and progressive, the sequestration process was delayed for 1 year, and sequestration was observed in a small number of patients (28.9% of patients). Cavernous sinus thrombosis, facial vein thrombophlebitis, removal of facial and jawbones, loss of vision, and other serious injuries are complications that can lead to disability and death in patients, reducing the quality of life [41–43].

Turbin described the clinical condition of 2 adolescents with polysinusitis, orbital cellulitis, periorbital edema, local hemorrhage, superior ophthalmic venous thrombophlebitis, cavernous and dural venous sinus, facial venous thrombosis, retromaxillary, and intracerebral radiological changes due to COVID-19. Patients underwent endoscopic frontal sinusotomy, total ethmoidectomy, upper jaw antrostomy, and removal of thickened, purulent, polypous mucosa. No fungi were observed in the cultures, gram-positive cocci, mainly C beta-hemolytic streptococci were grown [44]. Hypercoagulability in COVID-19 has been shown to lead to ocular vascular thrombosis, leading to blindness, as well as observed other ophthalmic complications (symptoms of dryness, foreign body sensation, pain, conjunctivitis, decreased visual acuity) [45–47].

#### 3.5. Opportunistic deep infections

Abuse and overuse of drugs in the treatment of coronavirus disease can lead to the pathogenicity of saprophytic bacteria and fungi in the body. Invasive fungi have also been reported in the literature as a cause of osteonecrosis. Naturally, the constant and consistent use of antibiotics promotes the development of fungi. Fungi belonging to the family Mucorales are highly adhesive and cause mucormycosis. Phygomycetes and Zygomycetes, which belong to this family, have a high degree of adhesion-lethality. Although these fungi are found in the nasal mucosa in the form of saprophytes, they become aggressive and cause disease in uncontrolled diabetic patients, in cases of hemodialysis, immunodeficiency, when taking high doses of glucocorticosteroids, in presence of burns and injuries, and other concomitant diseases [48–52].

Moorthy et al. observed facial and jaw bone necrosis, inflammation, vision loss, ptosis, sinusitis, palatal and alveolar necrosis in 18 patients with COVID-19 in India. In this case, the long-term treatment of patients with glucocorticoids and the proliferation of uncontrolled diabetes fungi are the main cause of the development of mucormycosis. Mucorales and in 2 cases Aspergillus fungi have been reported to be the cause of unpleasant profound changes. 14 patients underwent necrotic upper jaw removal surgery, all patients underwent endoscopic sinus surgery, and 9 patients underwent intracranial extension. Occlusion of the central ciliary artery and retinal artery due to this disease was the main cause of blindness in 12 patients, and 7 patients had to have their eyes removed to prevent the spread of the fungus to the base of the brain [53].

Waizel-Haiat observed thickening of the mucous membrane in the maxillary, ethmoidal, sphenoidal, and lateral sinuses in MSCT, and

subsequent necrotic changes in a 24-year-old woman who underwent Covid-19 on the background of symptoms such as the left eyelid, periorbital edema, ptosis, and decreased sensation on this side. Rhino-orbital-cerebral mucormycosis and other complications of Covid-19 resulted in the death of the patient. Rhizopus fungus has been reported to be the cause of the disease [54]. Amanda Werthman: in a Somali woman, the clinical course of Covid-19 was characterized by psychological disorders such as ptosis, ophthalmoplegia, a dry black film on the palate, which the doctor described as rhino-orbital-cerebral mucormycosis, staphylococci were found along with fungi in the cultured bioplate [55].

Alekseyev et al. observed the brain abscess, changes in the area of the temporal lobe, cavernous sinus due to mucormycosis in a 41-year-old man. Due to rhinocerebral mucormycosis, the patient had partial removal of the nasal septum, complete sinus cavity, sphenoidal and ethmoidal bones, palatal bone, and other necrotic tissue [56].

Similar conditions lead to deep and irreversible changes that damage the brain and nerves through the nasal and nasal adjacent cavities. In addition to the rhinocerebral form, it can cause disease in the lung, gastrointestinal, skin, and disseminated cases [57–59]. Increased blood glucose in patients, ketoacidosis, acidic shift of pH reduce the resistance of neutrophils to normal activity, ie against fungi and bacteria. The change in pH releases iron-protein complexes, which causes fungi to take advantage of free iron and become more active. In this disease, along with osteonecrosis of the maxillofacial bones, severe ophthalmological (loss of vision, ptosis, diplopia, periorbital edema, apex orbital syndrome) and neurological (cranial nerve palsy) and psychological changes are noted. In all cases, surgical intervention combined with medication is required [60–64].

#### 4. Conclusion

Thus, serious complications are observed in the facial area due to Covid-19 disease and/or its treatment. Most of them are directly or indirectly related to drugs that occur during treatment. The individual approach to each patient in the treatment of such conditions, the choice of optimal drugs by doctors leads to the prevention of many complications. From small changes in the oral cavity to osteonecrosis of the face and jaw and other changes in the body require long-term follow-up and thorough scientific examination. Of course, this short period of 1 or 2 years is not enough for long-term follow-up of some facial-jaw area complications — such as osteonecrosis or osteomyelitis — so this analysis should be continued and cohort, randomized trials should be carried out.

#### Financial support

This research did not receive any specific grant from funding agencies in the public, commercial, or not-for-profit sectors.

#### Declaration of competing interest

The authors declare that they have no competing or financial interests, either directly or indirectly, in the products listed in the study.

#### Acknowledgments

All authors participated in the research process and data collection. All authors performed all tissue analyses and participated equally in the revisions of this work and the writing and review of this article.
