Purpose: Although there is ample data about the prevalence of diabetes in the Middle East, little is known about the prevalence and features of autoimmune diabetes in this region. The aim of this study was to investigate the prevalence and metabolic characteristics of latent autoimmune diabetes in adults (LADA) amongst Yemeni Type 2 DM patients.

Patients and Methods: In this cross-section study, 270 Type 2 DM patients aged 30–70 years were recruited from the National Diabetes Center, Al-Thowra Hospital, Sana'a city, during the period November 2015 to August 2016. All Type 2 DM patients were diagnosed within 5 years and who did not require insulin for a minimum of 6 months following diagnosis. Levels of glutamic acid decarboxylase autoantibodies (GADA) were measured in all patients, and LADA was diagnosed in patients testing positive for anti-GAD antibodies. Further, biochemical analysis was carried out including fasting blood glucose (FBG), glycated haemoglobin (HbA1c), insulin, and lipid profile. Insulin resistance (HOMA-IR) and β -cell function (HOMA- β) were calculated.

Results: The prevalence of LADA, as defined by GADA-positive, amongst patient with Type 2 DM was 4.4%; with no significant difference in the prevalence between male (5.8%) and female (3.4%). LADA patients were younger than GADA-negative Type 2 DM. Body mass index, waist circumference, insulin and HOMA- β were significantly lower in LADA patients, whereas triglyceride, cholesterol, HDL-c and HOMA-IR were non-significantly lower with respect to Type 2 DM. In contrast, FBG and HbA1c were significantly higher in LADA patients. Moreover, the prevalence of metabolic syndrome was significantly lower in LADA as compared with Type 2 DM. Only 2 out of the 12 GADA-positive (16.7%) were on insulin treatment at the time of the study.

Conclusion: The prevalence of LADA in Yemeni Type 2 DM is lower than many of those reported in the literature, with no gender preference. Metabolic syndrome was significantly lower in LADA patients. Patients with LADA share insulin resistance with Type 2 DM but display a more severe defect in β -cell function, thus highlighting the importance of an early diagnosis of LADA, to correctly treat LADA patients, allowing safe and effective therapies.

Keywords: latent autoimmune diabetes in adults, Type 2 DM, metabolic syndrome, insulin resistance, glutamic acid decarboxylase antibody

Introduction

Latent autoimmune diabetes in adults (LADA) is a hybrid form of diabetes¹ that describes a subgroup of patients similar to Type 1 DM with markers of islet autoimmunity and shares features of Type 2 DM, including adult onset and insulin resistance.^{2–5} It is probably the most prevalent form of autoimmune diabetes in

Correspondence: Molham AL-Habori
Email malhabori@hotmail.com

general,⁶ and is characterized by genetic, phenotypic, and humoral heterogeneity, including different degrees of insulin resistance, high variability of the β -cell dysfunction and autoimmunity.^{3,7-9} However, the major characteristics of LADA are mainly focused on 3 points: presence of islet autoantibodies, age at diagnosis of at least 30 years, and insulin independence for at least 6 months after diagnosis.^{10,11} Epidemiological studies show that LADA may account for 2–12% of all cases of diabetes in adult population, which differs significantly in different ethnic groups.¹²⁻¹⁵ Moreover, 4–14% of patients diagnosed with Type 2 DM are positive for Type 1 DM associated autoantibodies which are diagnostic for LADA.^{4,5,12-18}

Patients with LADA are at high risk of progression to insulin dependency.¹⁹ A proportion of subjects with adult-onset autoimmune diabetes does not require insulin-therapy at the time of diagnosis and are clinically similar to patients with Type 2 DM. Although LADA appears similar to Type 2 DM, the typical presence of islet autoantibodies, such as GADA and tyrosine phosphatase antibody (IA-2A), indicate an autoimmune basis of LADA with a delayed progression compared with classic Type 1 DM.²⁰ The titre of antibody positivity especially GADA as well as the recognition of different patterns of autoantibody positivity can influence the clinical features of LADA and may be useful for diabetes classification and prediction of risk for insulin therapy.^{12,14,16,21} Overall, LADA patients with high GADA titer resemble Type 1 DM more closely, and those with low GADA titer resembles Type 2 DM patients in their metabolic characteristics and β -cell function during follow-up.²

The association of LADA with Type 1 DM and Type 2 DM still remains unclear and the precise definition of LADA has always been controversial.^{4,22} Striking heterogeneity has been recently highlighted as a relevant characteristic of LADA.³ Patients with LADA shares clinical and metabolic features with Type 1 and Type 2 DM as part of a range of variable severity of immune and metabolic dysfunction,²³ described as “end of the rainbow”.⁷ Latent autoimmune diabetes in adults has Type 1 DM-like autoimmune genetic components and Type 2 DM-like metabolic genetic components. When compared with classical Type 1 DM, LADA appears like the other extreme of the autoimmune diabetes spectrum, whereby genetic susceptibility, autoimmune response and non-insulin-necessity presentation constitute a mild form of autoimmune diabetes with pathological features closer to those of Type 2 DM than to those of Type 1 DM.³ The lack of optimal

treatment can result in deterioration of the autoimmune process, acceleration of β -cell loss, faster progression to insulin dependence, and an increased risk of complications.^{1,3} However, a personalized medicine approach is needed to achieve optimal metabolic control and preserve β -cell function, which is associated with a lower risk of occurrence of long-term diabetes complications.

In view of the fact that LADA represents an important clinical issue that needs to be addressed in order to facilitate improved glycemic control as well as the preservation of residual β -cell function together with its limited data on the prevalence and metabolic features in the Middle East region; the aim of this study was therefore to examine the prevalence and the metabolic characteristics of LADA in Yemeni Type 2 DM patients.

Patients and Methods

Study Design, Subjects and Data Collection

In this cross-section study, 270 Type 2 DM patients aged 30–70 years were enrolled from the National Diabetes Center, Al-Thowra Hospital, Sana'a city, from November 2015 to August 2016. All the Type 2 DM patients were diagnosed more than 2 months and less than 5 years, and who did not require insulin for a minimum of 6 months following diagnosis. Patients with secondary diabetes mellitus due to other conditions or under immunosuppression, pregnant women, heavy ketonuria (++) on urine test sticks, renal disease, or acute illness at the time of testing were excluded from this study. The study protocol was approved by the Institutional Review Board (IRB) of the Faculty of Medicine and Health Sciences, Sana'a University. Informed consent form was obtained from all individuals after explaining the purpose and nature of the study.

The patients' height and weight were measured and body mass index (BMI), defined as weight (kg)/ height squared (m^2), was calculated. Waist circumference (WC) was measured halfway between the lower rib margin and the anterior superior iliac spine. Blood pressure (BP) was measured in the seated position using an Omron IntelliSense Automatic Blood Pressure Monitor with at least a 10 min rest before period before the measurement. Two to three successive BP readings were obtained at 5 min intervals and averaged. Standardized questionnaire(s) was administered to collect patients' demographic and

clinical data including: age; age at onset of diabetes; duration of diabetes; family history of diabetes, the current treatment regimen that the patient is following; whether on insulin for glycaemic control; history of hypertension and dyslipidaemia.

Cases of LADA were defined as Type 2 diabetic subjects with diabetes-associated autoantibodies who did not develop ketoacidosis or did not require insulin for at least 6 months after diagnosis.¹¹ Metabolic syndrome (MetS) was classified according to the harmonized metabolic syndrome criteria,²⁴ whereby any 2 of the 4 following factors were required for the diagnosis of MetS among Type 2 DM patients: WC in man ≥ 94 cm and women ≥ 80 cm; triglyceride (TG) ≥ 150 mg/dl; HDL-cholesterol (HDL-c) in man < 40 mg/dl and women < 50 mg/dl; systolic blood pressure (SBP) ≥ 130 mmHg, and diastolic blood pressure (DBP) ≥ 85 mmHg).

Blood Collection and Biochemical Analysis

A fasting venous blood (5 mL) was collected from each patient after an overnight fast of more than 10 hours and divided into two vacuumed tubes; 4 mL into plain tubes for biochemical assay and 1 mL into a K₂EDTA tube for glycated haemoglobin (HbA1c). The serum from each sample was separated within 30 minutes and stored at -20°C for biochemical analysis. Haemolysate was prepared immediately for HbA1c determination within 2 hours of blood collection. Fasting blood glucose (FBG), TG, total cholesterol, and HDL-c were measured on an automated analyzer, the Cobas c501 (Roche Diagnostic, Germany), using their respective kits (Roche Diagnostic, Germany). Glycated haemoglobin (HbA1c) was measured on the Cobas c501 automated analyzer (Roche Diagnostic, Germany) using a turbidimetric inhibition immunoassay. Insulin was measured by an electrochemiluminescence immunoassay (ECL) on an Elecsys autoanalyzer (Roche Diagnostic, Germany). Insulin resistance (HOMA-IR) and β -cell function (HOMA- β) were calculated using the Homeostasis Model Assessment (HOMA2) Calculator v2.2 which is available from the Oxford Centre for Diabetes, Endocrinology, and Metabolism. Glutamic acid decarboxylase antibody (GADA) was measured using enzyme linked immunosorbent assays (Euroimmun AG, Luebeck, Germany), with the optimal cut-off value of positivity set at 10U/mL. The assay demonstrated good performance when tested in the 2015 Islet Autoantibody

Standardization Program (IASP) Workshops, with a sensitivity of 82% and specificity of 99%.

Statistical Analysis

The statistical analyses were performed on Social Package of Social Sciences (SPSS) version 11.5 (SPSS Inc, Chicago, IL, USA). The diabetic and metabolic syndrome parameters were skewed and therefore normalized by logarithmic transformation. Means were subsequently back transformed for presentation as geometric means and 95% confidence interval. Independent *t*-test was used to compare the diabetic and metabolic syndrome parameters between LADA and Type 2 DM. The treatment and pattern of metabolic syndrome factors among Type 2 DM and LADA were evaluated by Chi-square test. The significant differences were indicated if *p*-value was < 0.05 .

Results

Based on the detection of positive glutamic acid decarboxylase autoantibodies (GADA) ≥ 10 IU/mL, the prevalence of LADA among the 270 Type 2 DM recruited in this study was 4.4% (12 patients). Comparison of the demographic and biochemical parameters between GADA-negative Type 2 DM and LADA patients is depicted in Table 1. Of the 12 diagnosed LADA patients, seven (58.3%) were male and five (41.7%) were female; with no significant difference between them. Both age and age of onset were significantly ($p = 1 \times 10^{-5}$, $p = 8 \times 10^{-5}$) lower in LADA by 23% and 22% as compared with Type 2 DM. Moreover, BMI and WC were also significantly ($p = 1 \times 10^{-3}$, $p = 9 \times 10^{-3}$) lower in the LADA group by 17.9% and 9.9%, respectively. However, SBP and TG were non-significantly lower in the LADA group with respect to Type 2 DM by 3.4% and 19.3%; with no difference in DBP, cholesterol and HDL-c.

Fasting blood glucose and HbA1c were significantly ($p = 1 \times 10^{-4}$) higher in LADA group by 56.5% and 34% as compared with Type 2 DM. On the other hand, insulin and HOMA- β were significantly ($p = 1 \times 10^{-4}$) lower in LADA group by 53% and 74.5%, respectively; whereas HOMA-IR was non-significantly lower by 16.7%. The use of oral hypoglycemia, hypertension, or hyperlipidemia drugs was non-significantly different between the two groups (Table 1), with only 2 LADA patients being on insulin treatment. Moreover, diabetic family history was also non-significantly different between LADA and Type 2 DM.

Table 2 shows metabolic syndrome to be significantly ($p = 0.041$) lower in LADA patients (41.7%) with respect to Type 2 DM (70.5%). Similarly, increased WC was

Table 1 Demographic and Clinical Characteristics of Both Type 2 DM (GADA-Negative) and LADA (GADA-Positive)

	Type 2 DM (n = 258)	LADA (n = 12)	P value
Gender			
Male	114 (44.2%)	7 (58.3%)	
Female	144 (55.8%)	5 (41.7%)	0.252
Age (years)	48 (47–49)	37 (33–42)	1 × 10⁻⁵
Age at Onset (years)	45 (44–47)	35 (32–38)	8 × 10⁻⁵
BMI (kg/m ²)	28 (27–29)	23 (20–26)	1 × 10⁻³
Waist circumference (cm)	91 (89–92)	82 (75–88)	9 × 10⁻³
SBP (mmHg)	118 (117–120)	114 (106–122)	0.263
DBP (mmHg)	81 (80–83)	81 (75–87)	0.86
Triglyceride (mg/dl)	166 (156–176)	134 (101–176)	0.132
Cholesterol (mg/dl)	178 (172–185)	170 (146–200)	0.591
HDL-c (mg/dl)	54 (52–57)	52 (43–64)	0.729
FBS (mg/dl)	168 (160–176)	263 (211–327)	1 × 10⁻⁴

Diabetic family history	156 (60.5%)	7 (58.3%)	0.553

Notes: Data presented as geometric mean (95% Confidence interval). Mean significant difference $p < 0.05$ bolded.

Table 2 Pattern of Metabolic Syndrome Factors Among Type 2 DM and LADA

	Type 2 DM (n = 258)	LADA (n = 12)	P value
Metabolic syndrome	182 (70.5%)	5 (41.7%)	0.040
Increased waist circumference	167 (64.7%)	4 (33.3%)	0.031
High blood pressure	117 (45.4%)	4 (33.3%)	0.203
High triglyceride	159 (61.6%)	5 (41.7%)	0.14
Decreased HDL-c	103 (39.9%)	5 (41.7%)	0.498

Notes: Data presented as numbers (%). Significant difference $p < 0.05$ bolded.

significantly ($p = 0.031$) lower in LADA (33.3%) as compared with Type 2 DM (64.7%). However, increased BP and TG were non-significantly lower in LADA than Type 2 DM; with decreased HDL-c being non-significantly different between the two groups.

Discussion

The results presented in this study show the prevalence of LADA as defined by GADA positive amongst patient with Type 2 DM was 4.4%, which is similar to those reported in a Korean population study (4.4%)²⁵ and in a study from North America and Europe on drug-naïve Type 2 DM patients (4.2%).²⁶ However, the prevalence in our study was higher than the study conducted in South Africa (2.5%),²⁷ United

Arab Emirates (2.6%),¹² Malaysia (2.9%),²⁸ and lower than those reported in Sardinia (5.1%),²⁹ Tanzania (5.3%),³⁰ Sri Lanka (5.4%),³¹ China (5.9%)¹⁴ and the Cuttack region of Eastern India (7%).³² Higher prevalence was reported in studies done in Nigeria (11.9–14%)^{33,34} and Ghana (13.5%).³⁵ The UK Prospective Diabetes Study (UKPDS), which is one of the largest studies done in patients with Type 2 DM, reported a LADA prevalence of 11.2%.³⁶ Moreover, several European studies done in various groups of patients with clinically diagnosed as Type 2 DM in Finland, Australia, United Kingdom, and Sweden have found the frequency of GADA-positivity to range between 2 and 21%.^{3,37}

The differences in prevalence from the various studies may be attributed to ethnic variation, differences in sample

selection techniques, the use of different assay techniques for detection of GADA and varying diagnostic criteria or cut-off points. Moreover, differences in dietary habits, environmental factors, and phenotypic characteristics between European and Asian populations are reported to be responsible for the heterogeneity in the prevalence and characteristics of LADA in these 2 populations.¹⁹ In addition, population-based studies have reported lower prevalence of islet autoantibodies (including GADA) when compared with hospital-based studies.^{38,39} Currently, GADA is considered to be the most sensitive and specific biomarker in the diagnosis of LADA.^{5,40,41} Moreover, GADA was also demonstrated to be the most frequent islet autoantibody in both elderly and young LADA patients⁴² and was proposed that detection of GADA autoantibody alone is adequate when screening for LADA patients. On the other hand, a previous study reported that since GADA disappear after prolonged disease duration,⁴¹ it is likely that some LADA patients therefore appeared GADA-negative and classified as having Type 2 DM.

Moreover, our results showed no significant difference in the prevalence between male (5.8%) and female (3.4%) suggesting that there is no gender preference for LADA which is supported by earlier reports.^{18,34} However, other studies reported higher proportion of GADA-positive males than females amongst Type 2 DM patients.^{43,44} Our study also showed that LADA patients are younger than GADA-negative Type 2 DM which is in agreement with an earlier study;^{28,36} but differ from another study reporting no change in age.²⁶ One explanation could be that β -cell function declines rapidly in very young patients but slows in adolescence and adults.⁴⁵ Alternatively, genetic influences were reported to be determinants of age at presentation in LADA specifically the DRBI/DOBI genotype which is demonstrated in younger LADA patients.⁴⁶ Moreover, the susceptibility of the elderly LADA (≥ 60 years) was suggested to be associated with a single HLA-DQ haplotype while that of the young LADA (< 60 years) is associated with multiple HLA-DQ haplotypes.⁴² Other studies recognized that the common variants in TCFL72 gene may differentiate in young but not middle-aged GADA-positive and GADA-negative diabetic patients.⁴⁷ In addition, the higher prevalence of multiple autoantibodies in younger patients may be a possible cause for disease onset earlier in life.⁴⁸ A recent study, however, showed no differences in age at

diagnosis, duration of diabetes, or ethnic distribution was observed between GADA-negative and positive patients.⁴⁹

Both BMI and WC of our LADA patients were significantly lower than Type 2 DM, which is in agreement with those reported for European and Asian populations.^{1,5,33,50–52} In addition, several studies have reported significantly lower BMI in GADA-positive patients, irrespective of the ethnicity, age or gender distribution of the population studied.^{36,43,44} Along the same line, another study showed BMI and WC, though not significant, to be lower in LADA³³ and further suggested that there was a trend toward low values in GADA-positive individuals with Type 2 DM compared with the GADA-negative ones. A previous study reported that 76% of their LADA patients displayed BMI values corresponding to healthy individuals suggesting that the gradual β -cell destruction in LADA is insufficient to cause significant weight loss.⁵³ An earlier study observed that LADA patients with lower BMI show a more aggressive disease, which can lead to earlier β -cell exhaustion.⁵⁴ In accordance with this study, elderly LADA patients with lower BMI displayed a lower fasting and 2-hour postprandial C-peptide levels,⁴² indicating that elderly LADA patients with leaner body have poorer residual β -cell function than those who are obese. On the other hand, data from two large population-based studies showed that overweight and obesity are associated with an increased risk of LADA and that the risk is highest in individuals with a combination of overweight and family history of diabetes.⁵² The authors further suggested that the association with obesity appeared strongest in LADA with low GADA, and that LADA in 31–56% of individuals could be attributed to overweight/obesity, compared with 70–82% of all those with Type 2 DM.⁵²

The observed weight loss with high blood glucose levels might mean a patient is not getting the right amount of insulin or that the loss of glucose through the urine leads to losing calories as well as dehydration, thus leading to rapid weight loss. Moreover, poorly controlled diabetes can cause weight loss through muscle wasting, whereby insulin deficiency found in Type 2 DM both decreases muscle synthesis and increases its breakdown.⁵⁵ Alternatively, patients with LADA were reported to express higher dipeptidyl peptidase 4 (DPP 4) activity than those with Type 1 and Type 2 DM;⁵⁶ whereby its direct addition to skeletal muscle cells has been shown to inhibit insulin signaling,⁵⁷ suggesting that high DPP 4 activity can suppress protein synthesis in skeletal muscle. Moreover, LADA patients were reported to be at high risk

for the progressive loss of muscle mass and function compared to Type 2 DM.⁵⁸

In our study, TG, cholesterol and HDL-c were non-significantly lower in LADA with respect to Type 2 DM, which is in agreement with several studies,^{28,35,51,59} and in line with other studies reporting significant decrease in TG and cholesterol in LADA.^{5,60} The slight decrease in TG might be attributed to the observed associated decrease in insulin resistance (HOMA-IR). Moreover, HDL-c was reported to decrease with age in LADA patient indicating that LADA are at a higher risk of developing cardiovascular complications than Type 2 DM.⁶¹ Although much evidence has shown LADA patients to have lower BMI, waist-hip ratio, total cholesterol, and TG levels than those with Type 2 DM, some researchers have found that LADA and Type 2 DM were not distinct disease entities beyond the differences explained by BMI.⁶²

Overall, our study showed MetS to be significantly lower in LADA with respect to Type 2 DM, which is in agreement with previous studies.^{1,31,60-65} The lower MetS in our LADA patients is in concordance with the observed lower risk factors (BMI, TG and BP), and may be attributed to the lower HOMA-IR. A recent study suggested that insulin resistance may account for the residual MetS risk in LADA patients and support the use of insulin sensitizers in LADA.⁶⁵ Metabolic syndrome was also reported not to be a characteristic of autoimmune diabetes and be less prevalent in patients with autoimmune diabetes than in control subjects when glucose was excluded as a variable.⁶¹ However, another study reported that elderly LADA patients had significantly more components of MetS than those with young LADA,⁴² and have similar MetS prevalence as compared with Type 2 DM patients. Consistent with this, up to 59.2% of elderly LADA patients have MetS,⁴² which was higher than the 41.9% reported in European LADA patients⁶¹ and the 31% reported in a Chinese study.⁶⁶ Analysis of the data stratified by GADA titre showed that more components of MetS were evident in elderly LADA patients with low titre of GADA.⁴² Therefore, the clinical phenotype of LADA patients varies considerably with GADA titre, whereby low-titre GADA patients are phenotypically more similar to those with Type 2 DM.^{6,16}

Fasting blood glucose and HbA1c in our LADA patients were significantly higher, which is in agreement with earlier studies,^{36,50,59,67} and in line with other studies reporting higher FBG and HbA1c levels, though non-significant, in LADA compared to Type 2 DM.^{33,51}

Individuals with GADA-positive were also reported to have a tendency towards a higher proportion of individuals with HbA1c above the optimal target range when compared with GADA-negative subjects.³³ A recent study suggested that the higher 9-year mean HbA1c levels in LADA patients' entirely explains the higher risk of microvascular complications in LADA patients.⁶⁸ The authors further suggested that HbA1c should be considered as a therapeutic target to prevent microvascular disease in LADA patients and that immediate and sustained implementation of strict glycemic control is essential for LADA patients to reduce their risk of microvascular complications. Previous UKPDS results showed that 1% reduction in HbA1c is associated with a 37% reduced risk of microvascular disease.⁶⁹ In addition, LADA patients were reported to have worse glycemic regulation than Type 2 DM patients, possibly due to the limited production of endogenous insulin.^{1,19,60,70} This may be attributed to the autoimmune destruction of the β -cells which has been reported to be present at the diagnosis of LADA.⁷¹

In our study, both insulin and HOMA- β were significantly lower in LADA, which is in agreement with earlier studies.^{1,9,31,35,51,52} These findings indicated that residual β -cell function in LADA patients was worse than in Type 2 DM patients and that the β -cell secretory function in LADA deteriorate over time at a 3-fold higher rate than in Type 2 DM.⁷² A recent study showed that about a quarter of LADA developed β -cell dysfunction in the first 8 years' duration, and that GADA titer was the most important discriminatory factor related to higher risk of development of β -cell dysfunction.⁷³ However, another recent study suggested that individuals with low levels of GADA and absence of other antibodies do not experience progressive deterioration of β -cell function over a 21-month timeframe.⁷⁴ The impaired β -cell function may be attributed to an autoimmune-mediated β -cell dysfunction with a loss of β -cell mass,⁷⁵ which is considered as the main pathogenesis of LADA.¹¹ Other contributing factors include the persistent and significant hyperglycaemia in LADA patients which increases production of reactive oxygen species that is considered to mediate glucose toxicity of β -cell and induce β -cell apoptosis.⁷⁶ This abnormal and irreversible pancreatic β -cell damage caused by prolonged exposure to supraphysiological glucose results in decreased insulin gene expression and decreased insulin synthesis and secretion.⁷⁶ Moreover, a number of studies have shown that LADA patients tend to have a more pronounced loss of C-peptide and an increased likelihood

of insulin treatment compared with Type 2 DM patients.^{5,14,17,59,77} Recently, the decline pattern of C-peptide in LADA patients was demonstrated to be biphasic with an initial rapid linear progression followed by a stable mode.⁷³

The lower HOMA- β in our LADA patients with respect to previous studies conducted in other LADA populations^{36,68} might be explained in view of the fact that our Type 2 DM patients were diagnosed more than 2 months and less than 5 years and therefore their β -cell mass is much affected (12%); whereas those of other populations the participants were newly diagnosed Type 2 DM in which their β -cell mass was still preserved and not much affected (\approx 40%). In addition, almost all our LADA patients were not on insulin treatment. Consistent data from randomized clinical trials showed the importance of an early initiation of insulin therapy in LADA avoiding the use of secretagogues like sulphonylureas.⁷⁸ Generally, a higher proportion of GADA-positive patients were receiving insulin therapy when compared with those who were GADA-negative.³³ However, in our study only two out of the twelve GAD-positive (16.7%) were on insulin treatment, which is in line with several studies reporting 15%, 18% and 37% of their LADA patients were on insulin at the time of the study.^{34,77,79}

Insulin resistant (HOMA-IR) was non-significant lower in our LADA patients by 16.7%, which is in agreement with various studies from Asia and Western countries reporting that LADA is being characterized by insulin resistance, but to a lesser extent than Type 2 DM;^{4,51,52,62,80,81} which has been attributed to differences in BMI.^{62,80} The non-significant decrease observed in our LADA patients is likely to be attributed to the lower power (only 12 LADA) and not because of the absence of difference between the two studied groups. Thus, confirming that LADA patients still share insulin resistance with Type 2 DM but display a more severe defect in β -cell function.⁸² In contrast, a previous study showed insulin resistance to be significant higher in LADA patients.²⁸ This discrepancy with our results might be due to differences in treatment profile of subjects whereby their patients were already on insulin therapy whereas our patients were mostly on oral hypoglycaemic agents. Recently, elderly LADA patients were reported to display higher insulin resistance than those with young LADA patients but were not significant different from that in Type 2 DM patients.⁴² Moreover, the contribution of insulin resistance to the development of LADA was shown to depend on the degree of

autoimmunity, whereby LADA patients with less autoimmune activity as indicated by low GADA levels tend to be more insulin resistant than those with high GADA levels.⁵²

To the best of our knowledge, this is the first study to evaluate patients with LADA in Yemen. However, our study has some limitations. First, this was a hospital-based study, and selection of the study population may have had some bias. Second, the median disease duration was 0.9 year in GADA-positive (LADA) patients, while it was longer (2 years) in GADA-negative (Type 2 DM) patients. Third, since only GADA-positivity was considered for the diagnosis of LADA we cannot exclude the possibility that analysis of other antibodies (eg, islet antigen-2 antibody, insulin autoantibody, and zinc transporter 8) could contribute to the overall prevalence, particularly among those with GADA-negative. Fourth, the incidence and clinical features of autoimmune diabetes may vary between regions and ethnicities. Fifth, due to the small sample size of the LADA group, the results of the current study cannot be generalized and because of this lower power the absence of significant differences in some variables (eg, HOMA-IR) between LADA and Type 2 DM may not be because of the absence of differences between the two groups.

Conclusion

The results showed the prevalence of LADA based on the positivity of glutamic acid decarboxylase autoantibodies in Yemeni Type 2 DM is lower than many of those reported in the literature with no gender preference. Compared with GADA-negative Type 2 DM, LADA patients had earlier onset of diabetes and lower prevalence of metabolic syndrome. LADA patients share insulin resistance with Type 2 DM but display a severe defect in β -cell function. The results highlight the importance of an early diagnosis of LADA, which would avoid patients receiving unnecessary oral medication, allowing safe and effective insulin therapies as well as helping to predict the disease course and reducing long-term diabetes complications. Further epidemiological and clinical studies with larger sample sizes will demonstrate the prevalence and increase awareness of LADA.

Diabetes, Metabolic Syndrome and Obesity: Targets and Therapy

Dovepress

Publish your work in this journal

Diabetes, Metabolic Syndrome and Obesity: Targets and Therapy is an international, peer-reviewed open-access journal committed to the rapid publication of the latest laboratory and clinical findings in the fields of diabetes, metabolic syndrome and obesity research. Original research, review, case reports, hypothesis formation, expert opinion

and commentaries are all considered for publication. The manuscript management system is completely online and includes a very quick and fair peer-review system, which is all easy to use. Visit <http://www.dovepress.com/testimonials.php> to read real quotes from published authors.

Submit your manuscript here: <https://www.dovepress.com/diabetes-metabolic-syndrome-and-obesity-targets-and-therapy-journal>
