Abstract Expression of crassulacean acid metabolism (CAM) is characterized by extreme variability within and between taxa and its sensitivity to environmental variation. In this study, we determined seasonal fluctuations in CAM photosynthesis with measurements of nocturnal tissue acidification and carbon isotopic composition ($\delta^{13}\text{C}$) of bulk tissue and extracted sugars in three plant communities along a precipitation gradient (500, 700, and 1,000 mm year $^{-1}$) on the Yucatan Peninsula. We also related the degree of CAM to light habitat and relative abundance of species in the three sites. For all species, the greatest tissue acid accumulation occurred during the rainy season. In the 500 mm site, tissue acidification was greater for the species growing at 30% of daily total photon flux density (PFD) than species growing at 80% PFD. Whereas in the two wetter sites, the species growing at 80% total PFD had greater tissue acidification. All species had values of bulk tissue $\delta^{13}\text{C}$ less negative than $-20\text{\textperthousand}$, indicating strong

CAM activity. The bulk tissue $\delta^{13}\text{C}$ values in plants from the 500 mm site were 2‰ less negative than in plants from the wetter sites, and the only species growing in the three communities, *Acanthocereus tetragonus* (Cactaceae), showed a significant negative relationship between both bulk tissue and sugar $\delta^{13}\text{C}$ values and annual rainfall, consistent with greater CO₂ assimilation through the CAM pathway with decreasing water availability. Overall, variation in the use of CAM photosynthesis was related to water and light availability and CAM appeared to be more ecologically important in the tropical dry forests than in the coastal dune.

Introduction

Crassulacean acid metabolism (CAM) is characterized by a nocturnal CO₂ uptake by the enzyme phosphoenolpyruvate carboxylase (PEPc), which represents phase I within the four phases of CAM as defined by Osmond (1978). This nocturnal uptake of CO₂ via PEPc forms C₄ acids, which are decarboxylated during the daytime and generate an elevated intercellular CO₂ concentration when stomata are closed (phase III). Between these two phases, there are transitional periods of net CO₂ uptake at the beginning (phase II) and at end (phase IV) of the day, when both PEPc and RUBISCO can contribute to CO₂ assimilation (Lütge 1987; Cushman 2001; Dodd et al. 2002). Environmental factors such as light intensity, relative humidity, nocturnal temperature, and water availability affect the proportion of CO₂ uptake at night via PEPc or directly during the day via RUBISCO (Griffiths 1992; Cushman and Borland 2002; Taybi et al. 2002; Jian-Ying et al. 2005).

The nocturnal CO₂ uptake mechanism found among CAM species generally improves water-use efficiency because of reduced transpiration rate during the night (Cushman and Borland 2002). One hallmark of CAM plants is the remarkable flexibility of the basic metabolic framework described above, which varies in terms of the proportion of CO₂ assimilated through the CAM and C₃ pathways, among taxa, and in response to environmental conditions (Holtum and Winter 1999; Holtum 2002; Taybi et al. 2002; Cushman and Borland 2002; Dodd et al. 2002; Winter and Holtum 2007; Winter et al. 2008), and may confer an ecological advantage for surviving in habitats with seasonal variation in resource availability (Griffiths 1992; Cushman and Borland 2002; Lütte 2004). Therefore, CAM plants are likely to vary in the balance of CO₂ assimilation by RUBISCO versus PEPc along environmental gradients, and such variation may provide some advantage over other species within the community.

Investigations of carbon isotopic composition ($\delta^{13}\text{C}$) can yield information regarding long-term and daily changes in the proportion of CO₂ fixed during the night or day (Griffiths 1992). The $^{13}\text{C}/^{12}\text{C}$ ratio is an indicator of these changes in the assimilation of CO₂ because the enzyme responsible for net CO₂ uptake in the dark, PEPc, discriminates less against ^{13}C than RUBISCO, the enzyme responsible for most net CO₂ uptake during the day. The changes in $\delta^{13}\text{C}$ in CAM plants thus depend on: (1) the contribution of CO₂ fixed directly by RUBISCO in the light (Phase II and IV); (2) the proportion of respiratory CO₂ fixed during phase I in the dark by PEPc; and (3) the extent of leakage during the decarboxylation (phase III), allowing RUBISCO discrimination to be expressed (Griffiths et al. 1990, 2007; Griffiths 1992). CAM plants with CO₂ uptake almost exclusively at night would, thus, be expected to show $\delta^{13}\text{C}$ values around $-11\text{\textperthousand}$, whereas if all the CO₂ is fixed directly by RUBISCO the values of $\delta^{13}\text{C}$ would be approximately $-27\text{\textperthousand}$ (O'Leary 1988). A shortcoming of using whole-tissue carbon isotope surveys to obtain an integrated value of the contribution of dark and light CO₂ fixation to the total carbon gain is that, in the absence of measurements of acidity or CO₂ exchange, it is unclear where C₃ ends and CAM begins. Species with values of $\delta^{13}\text{C}$ characteristic of C₃ plants have been reported to obtain up to one-third of their carbon through CAM activity (Winter and Holtum 2002; Silvera et al. 2005; Griffiths et al. 2007).

Many studies document a wide range in the magnitude of CAM expression that can be induced by water limitation, high temperatures, and high light availability in different species (Kluge et al. 2001; Winter and Holtum 2002, 2005; Pierce et al. 2002; Holtum et al. 2004; Winter et al. 2005; Griffiths et al. 2007; Herrera 2009; Silvera et al. 2009; Vargas-Soto et al. 2009). Moreover, ecophysiological

surveys are a powerful tool to obtain insights leading to a better understanding of the adaptive significance of CAM (Kluge et al. 1997, 2001). In this paper, we present a comparative survey of CAM activity in three plant communities of the Yucatan Peninsula along a gradient of water availability. This is to our knowledge one of the few comparative ecophysiological investigations of CAM activity of different species in different ecosystems. The aims of the present study were: (1) to determine the relative ecological importance of CAM species as a function of precipitation; (2) to determine seasonal fluctuations in CAM photosynthetic activity through nocturnal acid accumulation in plants growing on a precipitation gradient and in different light microenvironments; (3) to evaluate the extension and degree of CAM activity through isotopic variation in $\delta^{13}\text{C}$ of bulk photosynthetic tissue and sugars along a precipitation gradient.

Materials and methods

Study site and species

The Yucatan Peninsula experiences a seasonally-dry tropical climate and contains a north-south precipitation gradient of 500–2,000 mm. A marked dry season from March to May, when most of the trees are leafless, is separated from the rainy season between June and October, and an early dry season from November to February, which is often characterized by up to 3-day events of strong winds ($>80 \text{ km h}^{-1}$), little rainfall (20–60 mm) and low temperatures ($<20^\circ\text{C}$; Orellana 1999).

This study was conducted in three sites: (1) the coastal dune scrubland of San Benito ($21^\circ19'10''\text{N}$, $89^\circ30'40''\text{W}$), which receives approximately 500 mm of annual rainfall, and has a mean annual temperature of 26°C (Orellana 1999); (2) Dzibilchaltún, National Park ($21^\circ05'\text{N}$, $89^\circ35'\text{W}$), a tropical dry deciduous forest with a mean annual rainfall of 700 mm and temperature of 25.8°C (Thien et al. 1982); and (3) Cuxtal Ecological Reserve ($20^\circ47'\text{N}$, $89^\circ49'\text{W}$), a tropical dry deciduous forest, with a mean annual rainfall of approximately 1,000 mm, and a mean annual temperature of 25.5°C (Chnaid 1998). The sites were selected because of high CAM species diversity and relatively little disturbance compared to ecosystems of the northern Yucatan (Espejel 1987; Rico-Gray et al. 1988; Ceccon et al. 2002; White and Hood 2004).

At each site, species in families with previous reports of CAM (Winter and Smith 1996), such as Agavaceae, Bromeliaceae, Cactaceae and Orchidaceae, were selected for investigation. Only one epiphyte species was selected, *Myrmecophila christinae*, and all other species were terrestrial (Table 1).

Community structure and relative importance value of CAM species

The point-centered quarter method was used to determine community structure and captures the most abundant species in a rapid and reliable way (Mueller-Dombois and Ellenberg 1974). We used two 100-m-long transects and selected 20 sampling points at random in each transect. At each sampling point, four quarters were established through a cross formed by two lines. The distance to the midpoint of the nearest individual from the sampling point was measured in each quarter. For each sampling point, the species identity and the cover or dominance of the individual were recorded. The individuals considered were those that had a minimum height of 10 cm; Poaceae and annual species were not considered. The relative importance value (RIV) was used to estimate the relative importance of plant species in the three communities defined as: RIV = Relative density + Relative coverage + Relative frequency (Skeen 1972; Mueller-Dombois and Ellenberg 1974).

Nocturnal tissue acidification

At each study site, ten individuals of each species were randomly selected, five growing at ca. 80% of total daily photon flux density (PFD) and five growing at ca. 30% of total daily PFD, which was measured with gallium arsenide phosphide photodiodes (Hamamatsu, Bridgewater, NJ, USA), previously calibrated against a quantum sensor (LI190S; LI-COR, Lincoln, NE, USA) connected to a datalogger (CR21X; Campbell Scientific, Logan, UT, USA) and placed 5 m above the ground in a non-shaded location. The minimal distance among individuals was 5 m.

Two samples of one leaf or stem were taken with a cork borer (1.5 cm diameter) at dusk, and before dawn the following day during the rainy (15–18 October 2005), early dry (7–10 February 2006) and dry (25–28 May 2006) seasons. Environmental conditions at the time of sampling were: during the rainy season, a daily average precipitation of 27.4 mm in the three sites (15 October 2005), minimum temperature 20°C (San Benito), maximum temperature 34°C (Dzibilchaltún and Cuxtal); during the early dry season no rainfall during the sampling period and previous week, minimum temperature 10°C (San Benito), maximum temperature 32°C (Cuxtal); during the dry season little rainfall at Cuxtal (3.5 mm) during the sampling period; minimum temperature 22°C (San Benito); maximum temperature 35°C (Cuxtal). Samples were frozen until transported to the laboratory, then boiled in 10 ml of distilled water for 10 min, and, after adding 50 ml of distilled water, ground with a mortar and pestle, and titrated with 0.01 N NaOH to pH 7 (Osmond et al. 1994) measured with an

electronic pH meter (Model 744; Metrohm, Herisau, Switzerland). Nocturnal tissue acidification (ΔH^+) was estimated from the hydrogen ion concentration (H^+) at dawn minus H^+ at dusk.

Carbon isotopic composition

During the rainy season (18 October 2005), five samples of leaf or stem were taken from the same individuals at the time when the predawn samples for tissue acidity were taken. The samples were dried in an oven at 80°C for 48 h and homogenized to a fine powder using a mortar and pestle. Samples for carbon isotopic composition of bulk tissue were prepared as 3-mg samples rolled in tin capsules (Craven et al. 2001; Pierce et al. 2002; Winter and Holtum 2002).

Whereas carbon isotopic composition ($\delta^{13}\text{C}$) of bulk tissue represents the time-integrated proportion of CO_2 assimilated through the CAM versus C_3 pathway in CAM plants, we also measured the extractable sugar fraction, which more closely reflects the photosynthetic discrimination against $^{13}\text{CO}_2$ over the previous 1–2 days allowing an indication of how plants are responding to environmental conditions over a shorter period (Ehleringer et al. 2004; Hu et al. 2010). The sugar extraction and purification was performed according to Brugnoli et al. (1998) and modified as follows: approximately 50 mg of oven-dried leaf material was mixed with 5 cm³ of distilled de-ionized water (vortex for few seconds), and centrifuged for 20 min at 12,000g. The supernatant was then decanted through ion-exchange resins (Dowex 50WX8-100, 1X2, Cl⁻-form; Sigma-Aldrich, St. Louis, USA) to isolate the neutral fraction (mostly sugars). After freeze-drying the samples, 0.8–2.0 mg of dried sugars were prepared in sample tins for isotopic analysis. $\delta^{13}\text{C}$ was determined on an elemental analyzer (ANCA-SL; PDZ Europa, Crewe, UK) interfaced with a continuous flow isotope ratio mass spectrometer (model 20/20; PDZ Europa) at the University of California, Berkeley, Center for Stable Isotope Biogeochemistry (CSIB). Long-term external precision for these analyses are $\pm 0.22\%$ for $\delta^{13}\text{C}$. The abundance of ^{13}C in each sample was calculated relative to the abundance of ^{13}C in internal standards that had been calibrated against Pee Dee belemnite. Relative abundance was determined using the relationship (Ehleringer et al. 2004): $\delta^{13}\text{C} (\%) = [({^{13}\text{C}}/{^{12}\text{C}} \text{ of sample}) / ({^{13}\text{C}}/{^{12}\text{C}} \text{ of standard}) - 1] \times 1,000$.

Statistical analysis

A three-way analysis of variance (ANOVA) with ‘repeated measures’ (ANOVAR; Potvin et al. 1990; Valdez-Hernández et al. 2010) was used to compare the tissue acidity among light levels, seasons and species within each

site. Differences in carbon isotopic composition among sites and between light levels were tested using a nested ANOVA, where the different light levels were nested within each site, and using mean species values for bulk tissue and sugar $\delta^{13}\text{C}$. Means were compared with a Tukey test and all analyses were performed using Statistica v. 7.0 (StatSoft, Tulsa, OK, USA). Linear regression was utilized to describe the relationship of both bulk tissue and extracted sugar $\delta^{13}\text{C}$ values for *Acanthocereus tetragonus* as a function of annual rainfall.

Results

Relative importance of CAM species

In the 500 mm site (coastal dune scrubland, San Benito), 10% of species had CAM, which represented 19% of the relative importance value (RIV) in the plant community. In this site, one CAM species (*Agave angustifolia*) was 1 of the 15 species with the highest RIV (16% RIV; Fig. 1a), while *Acanthocereus tetragonus* and *Opuntia dillenii* contributed only 3% of the RIV in the community. In both tropical dry deciduous forest communities, 15% of species were CAM and represented 35 and 20% of the RIV for the 700 mm site (Dzibilchaltún) and the 1,000 mm site (Cuxtal), respectively. Four CAM species were among the 16 species with the highest importance value in these two communities: in the 700 mm site, these were *Agave angustifolia*, *Nopalea inaperta*, *Bromelia karatas* and *Stenocereus eichlamii*; whereas in the 1,000 mm site, these were *S. eichlamii*, *N. inaperta*, *B. karatas*, and *Pereskia scandens*. *Acanthocereus tetragonus* was not within the 15 species with the highest RIV, but it was always among the 24 species of most importance in both forest communities (Fig. 1).

Nocturnal tissue acidification

Tissue acidification was significantly different among seasons in the three sites, with the greatest values during the rainy season ($P < 0.0001$ for the three sites; Table 1). In the 500 mm site, the lowest tissue acidification values were during the dry season, and in both wetter sites, the lowest values were during the early dry season. During the rainy season, tissue acidification was significantly different for plants growing in the two light microclimates in the three communities ($P < 0.0001$ for the 500 mm site, and $P < 0.05$ for the 700 mm and the 1,000 mm sites, respectively; Table 1). At the 500 mm site, plants growing at 30% of total daily ambient PFD showed higher acidity values than those growing at 80% of total PFD ($P < 0.0001$; Table 1). In both forest communities, tissue

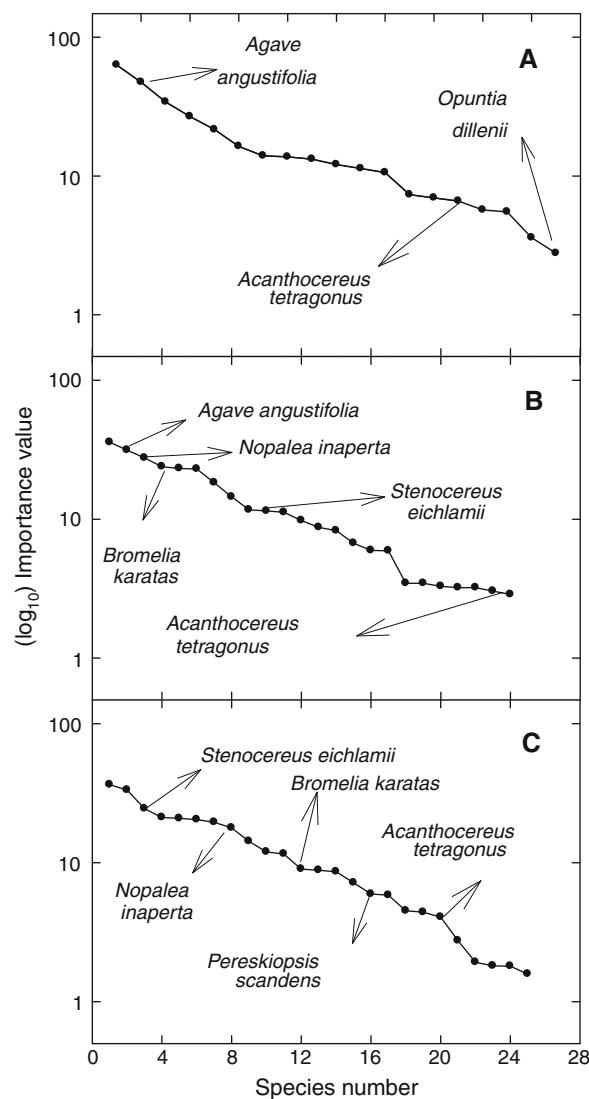

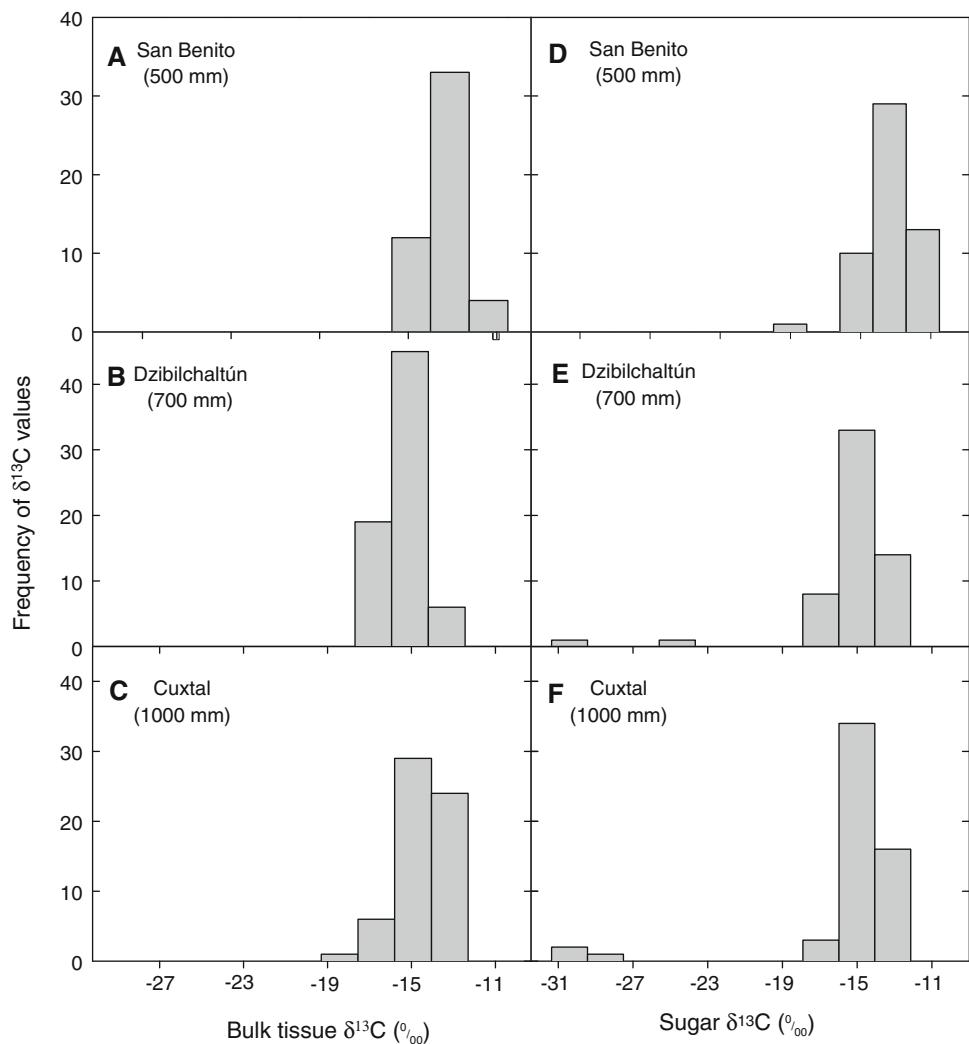

Fig. 1 Relative ecological importance of CAM species in the coastal dune of San Benito (a) and the tropical dry deciduous forests of Dzibilchaltún (b) and Cuxtal (c). Each symbol corresponds to a different species in the communities

acidification during the rainy season was greater for plants growing at 80% PFD than plants growing at 30% PFD ($P = 0.020$ and $P = 0.047$, for the 700 and 1,000 mm sites, respectively).

Carbon isotopic composition of bulk tissue fractions

All plants in all sites showed bulk tissue leaf $\delta^{13}\text{C}$ values typical of strong CAM, less negative than $-20\text{\textperthousand}$ (Fig. 2), with the least negative bulk tissue $\delta^{13}\text{C}$ values (-11 to $-15\text{\textperthousand}$) in the 500 mm site (Fig. 2a) and the most negative values (-12 to $-19\text{\textperthousand}$) in the 1,000 mm site (Fig. 2c). Plants growing in the 500 mm site were more enriched in ^{13}C ($P < 0.05$), with mean $\delta^{13}\text{C}$ of bulk tissue approximately 2\textperthousand less negative than plants growing in the forest

Fig. 2 Frequency of bulk tissue (**a–c**) and sugar (**d–f**) $\delta^{13}\text{C}$ values for individuals of 12 CAM species in the coastal dune of San Benito (**a, d**) and the tropical dry deciduous forests of Dzibilchaltún (**b, e**) and Cuxtal (**c, f**). Each bar represents a 2‰ range of $\delta^{13}\text{C}$

communities. There was a significant negative relationship between annual rainfall and leaf $\delta^{13}\text{C}$ values for *Acanthocereus tetragonus*, the only species found in all three sites (Fig. 3a). No differences in bulk tissue $\delta^{13}\text{C}$ values were found between plants growing at 30 and 80% total daily ambient PFD in any of the three sites ($P > 0.05$).

Carbon isotopic composition of the sugar fraction

Similar to bulk tissue $\delta^{13}\text{C}$ values, in the 500 mm site, plants had sugar $\delta^{13}\text{C}$ values 2‰ less negative than plants in the other two sites ($P < 0.05$). The standard deviation from the mean of the $\delta^{13}\text{C}$ values of the sugar fraction in each species showed that *Acanthocereus tetragonus* had greater $\delta^{13}\text{C}$ variability than the rest of the species (Fig. 4). Similar to bulk tissue, $\delta^{13}\text{C}$ values of the sugar fraction for *Acanthocereus tetragonus* showed decreasing enrichment of ^{13}C of sugar with increasing precipitation (Fig. 3b). Moreover, *A. tetragonus* was the only species that showed significant differences in the $\delta^{13}\text{C}$ values of sugar between

the plants growing at 80 and 30% of total daily PFD in the coastal dune scrubland; plants that had the least negative values of $\delta^{13}\text{C}$ were those growing at 80% PFD in comparison with plants growing at 30% PFD ($P < 0.0001$; Fig. 5a). In the other two communities, this species did not show differences in $\delta^{13}\text{C}$ of sugar between light microenvironments ($P > 0.05$). Tissue acidification was significantly different between individuals of *A. tetragonus* growing at 80 and 30% of PFD in the coastal dune scrubland (Fig. 5b); individuals with the lowest acidity values were those growing at 80% PFD ($P < 0.0001$). No differences in tissue acidity were found between the plants of this species growing in both light conditions in the other two communities ($P > 0.05$; Fig. 5b).

Discussion

Our data demonstrate that carbon gain by CAM plants along this precipitation gradient was greatest in the wet

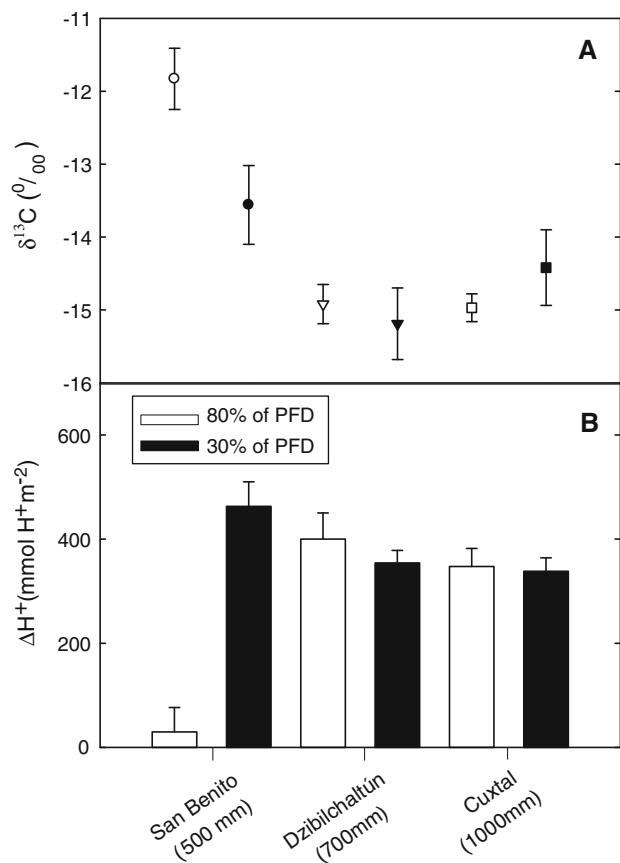

Fig. 5 Values of $\delta^{13}\text{C}$ of sugars (a) and tissue acidity (b) in three populations of *Acanthocereus tetragonus* in San Benito (circles), Dzibilchaltún (triangles) and Cuxtal (squares) growing at 80% of total daily photon flux density (PFD) (open symbols) or at 30% total PFD (closed symbols) during the rainy season

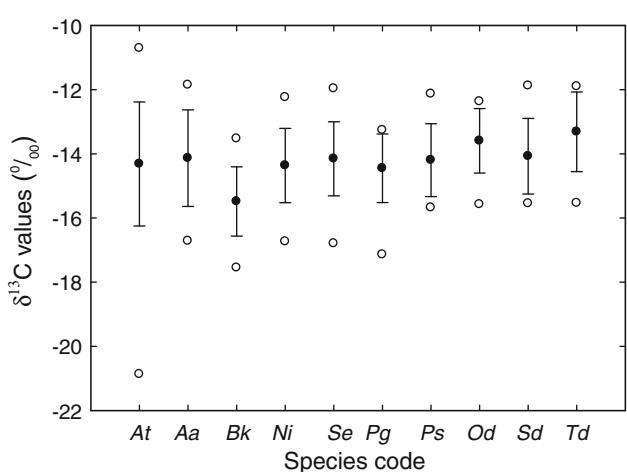

Fig. 4 Mean $\delta^{13}\text{C}$ values (closed symbols) of sugar \pm standard deviation and range (open symbols) of 10 CAM species. Key for the species code: *Acanthocereus tetragonus* (At), *Agave angustifolia* (Aa), *Bromelia karatas* (Bk), *Nopalea inaperta* (Ni), *Stenocereus eichlamii* (Se), *Pilosocereus gaumeri* (Pg), *Pereskiopsis scandens* (Ps), *Opuntia dillenii* (Od), *Selenicereus donkelaarii* (Sd), and *Tillandsia dasylirifolia* (Td)

season, indicating that seasonal water limitation has the potential to reduce carbon gain by approximately 75% at the relatively dry coastal dune site and by 50% in the wetter forest sites, when comparing tissue acidification in the dry season versus wet season. In addition, at the driest site, plants growing at lower light had greater rates of carbon gain, whereas in the two wetter sites, plants growing in the higher light microhabitat had greater rates of carbon gain. These results highlight a shift in the interaction between light and water availability along this gradient, in which we observed that, when water availability increases, plants were able to increase their tissue acidification at higher PFD. In addition, our $\delta^{13}\text{C}$ data showed greater proportional use of the nocturnal CO_2 uptake of the CAM species at the driest site (Fig. 2). Moreover, species importance values and the proportion of CAM species in the communities increased from the coastal dune to the tropical dry forests, suggesting a more favorable balance of light and water availability for CAM performance in the wetter, forested communities.

Tissue acidity is an indirect way to measure nocturnal CO_2 uptake, including direct CO_2 uptake and CO_2

produced during respiration and re-assimilation. Therefore, an increase in tissue acidity would indicate an increase in the CO₂ uptake (Nobel 1988, 1991; Osmond et al. 1994). Other CAM species also show an enhancement in their net CO₂ uptake and increase tissue acidity when well watered and a reduction of these two processes when droughted (Andrade et al. 2007, 2009). The reduction of tissue acidity during the dry season can be caused by higher nocturnal temperatures and greater water deficits together with higher PFD levels than during the rainy season (Cervera et al. 2007; Andrade et al. 2009). To avoid excess transpiration during the dry season, CAM species tend to show maximal stomatal opening later in the night reducing the amount of nocturnal increase of tissue acidity (Nobel 1985a, b, 1988; Nobel et al. 1991; Andrade and Nobel 1997; Lu et al. 2003; Cervantes et al. 2005; Cervera et al. 2007). Conversely, the reduction of tissue acidity during the early dry season could be caused by the reduction in the PFD (30 mol m⁻² day⁻¹) in comparison with that of the rainy and dry seasons (35 and 40 mol m⁻² day⁻¹, respectively). Although it has been reported that, for several desert CAM species, nocturnal acid accumulation increases up to a total daily PFD of about 30 mol m⁻² day⁻¹ and any reduction in PFD reduces net CO₂ uptake (Nobel 1988), lower water vapor pressure deficits in our study sites than in the desert could increase that PFD limit, allowing the plants to use more light without losing more water.

In the 500 mm site, plants growing at 30% of the total daily ambient PFD had greater tissue acidification than plants growing at 80% ambient PFD (Table 1). Nevertheless, in both forest communities, the greatest increase in tissue acidity was for plants growing at 80% PFD. These differences among plants of the three sites are likely due to differences in soil water potentials and water vapor pressure deficits. For example, after 30 days of drought during the dry season, soil water potential 15 cm below the surface was -22.4 ± 2.3 MPa for a coastal dune scrubland and -19.8 ± 1.6 MPa for a tropical dry deciduous forest (Cervera et al. 2007). In addition, in some CAM species, under light-saturating conditions, an increase in the photosynthetic capacity as a response to growth in high light without a proportional increase in the malate supply would predispose some plants to photoinhibition, causing drought stress to increase the negative effects of the high radiation (Skillman and Winter 1997). In our study, during the dry season, most species of the coastal dune site showed the lowest tissue acidity values (Table 1, Fig. 5) and less negative δ¹³C values than all other species for the two communities, indicating stomatal closure during phases II and IV of the CAM cycle and no contribution of RUBISCO to CO₂ uptake.

CAM species that showed significant differences in the tissue acidity growing in the two light microenvironments also had the highest relative importance value in the three

communities. One exception was *Acanthocereus tetragonus* (Fig. 1), which was the only species in the three communities with strong CAM photosynthesis and a high photosynthetic plasticity in the coastal dune. It has been proposed that, given the range in the magnitude of CAM expression that can be induced by water limitation in different species, the ecological significance of CAM induction would depend on its relative importance as a survival mechanism, rather than the direct contribution to growth and productivity of the species (Griffiths 1992; Cushman and Borland 2002; Lüttge 2004). Kluge et al. (2001) found that CAM species of Madagascar with the highest photosynthetic plasticity were the species most widely distributed across the island, and thus occupied a greater variety of environments, compared to CAM species with low photosynthetic plasticity, which occupied a more restricted set of environments.

CAM plants in the three communities showed bulk tissue δ¹³C values typical of strong CAM (δ¹³C values less negative than $-20\text{\textperthousand}$; Holtum et al. 2004; Silvera et al. 2005), but the δ¹³C values in plants from the coastal dune scrubland were 2\textperthousand less negative than those from plants of the forest communities (Fig. 2). The bulk tissue and sugar δ¹³C values for *Acanthocereus tetragonus*, which occurred in the three sites, showed a significant negative relationship with rainfall (Fig. 3). These data suggest that plants at drier sites decreased transpiration and stomatal conductance relative to photosynthesis, which would lead to the measured increase in δ¹³C values. Moreover, the duration of the phase II of CAM decreases under water stress (Griffiths 1992), which would also decrease the isotope discrimination, leading to less negative δ¹³C values. Similar results have been found in terrestrial plants from desert and tropical dry forest, and for epiphytes in a tropical cloud forest and three different secondary tropical dry forests where the carbon isotope ratios also increased with decreasing water availability (Ehleringer and Cooper 1988; Mooney et al. 1989; Hietz et al. 1999; Goode et al. 2010).

It has been proposed that the flexibility of CAM provides an advantage for acquisition of ecological niches (Lüttge 2004; Herrera 2009). In the present study, although all the species investigated in the three communities showed δ¹³C values typical of strong CAM, one species, *A. tetragonus*, which inhabited all three communities, showed the highest variability in δ¹³C values (Fig. 4). Members of the family Cactaceae have been considered as constitutive or obligate CAM species even at their early stages (Hernández-González and Briones-Villarreal 2007); although some studies suggest that the contribution of CAM to total carbon gain is small during the first developmental stages (Nobel 1988; Winter et al. 2008). The high variability of the strong CAM species, *A. tetragonus*, suggests that some cacti are able to respond to changes in the environment and inhabit more environments than other

cacti. More detailed field and laboratory studies on different life stages of these strong CAM plants would be required to fully understand their ecological role in these tropical plant communities.

Acknowledgments This work was supported by the grant Fondo Sectorial SEP-CONACYT 48344/24588 to J. L. A., a University of California Institute for Mexico and the United States grant to L. S. S., and a Consejo Nacional de Ciencia y Tecnología, Mexico Fellowship to M. F. R.
