## ABSTRACT

**Aims:** The aim of the current study was to determine the prevalence of grandmultiparity and the associated risks factors. **Methods:** Four hundred thirty grandmultiparas (parity 5 or more) were compared with multiparous population (parity 2-4) with regard to maternal age, gestational age, mode of delivery, fetal and maternal outcomes and inter-current medical and obstetrical problems. **Results:** There were significant association between grandmultiparity and adverse pregnancy outcomes such as cesarean delivery (OR=2.699, CI=2.072-3.515,  $p < 0.001$ ), fetal macrosomia (OR=1.675; 95% CI=1.004- 2.796,  $p = .048$ ), Diabetes mellitus (OR=1.634, 95% CI=1.076-2.481,  $p = 0.021$ ), and pregnancy induced hypertension (OR=1.838, 95% CI=1.054-3.204,  $p = .032$ ). No significant associations were seen in placenta abruption, placenta previa, preterm labor, postpartum hemorrhage and the frequency of admission to neonatal intensive care unit. No prenatal or maternal mortality was reported in this study. **Conclusion:** Grandmultiparity remains a major obstetrics problem. It is associated with many medical and obstetrical complications. In communities where large family is desirable it is important to address the value of family planning and conduction of meticulous antenatal care.

**Key words:** Grandmultiparity, Pregnancy outcome, Obstetric complications, Neonatal morbidity.

## 1. INTRODUCTION

Grandmultiparity has been considered an independent factor for increasing adverse outcome for both fetus and mother specially diabetes mellitus, antepartum hemorrhage, malpresentation, cesarean section rate, postpartum hemorrhage, iron deficiency anemia, and a high perinatal mortality rate AI JF [1]. More recent reports, however, have demonstrated that in the presence of good perinatal care, grand multiparity no longer need to be considered an obstetrical risk in the presence of satisfactory health care conditions [2,3]. The majority of the studies argued that grandmultiparas are more likely to be of old age which might be the reasons for increased morbidity and mortality. In our clinical practice, such factor is difficult to be removed because women's age is the most important biological variable that influences the reproductive events which we study.

In Saudi Arabia, large family is desirable for cultural reasons; consequently, a high incidence of grand multiparity is expected. The Fertility rate in Saudi Arabia was last reported at 2.81 in 2010, according to a World Bank report published in 2012 [4]. In addition, early age of marriage might be one of the reasons for this high incidence of grandmultiparas. The current study was conducted in a tertiary hospital where medical care is given free of charge

for all mothers. The aims of the current study were to determine the prevalence and to investigate the fetomaternal outcomes related to grandmultiparity.

## 2. METHODS AND SUBJECTS

In this retrospective study, the data were gathered from patient's case notes over a period of a 1-year from January 1, 2012 through December 31, 2012 at the Maternity and Children Hospital (MCH), Buraidah, Saudi Arabia in an attempt to determine the prevalence of grandmultiparity and its associated risks.

The MCH is a tertiary hospital where medical care is given free of charge. Uncomplicated cases received antenatal care at the level of primary health care centers, whereas complicated and referred cases are managed at the hospital. All deliveries took place in the hospital, and no home confinements were allowed.

In this study, a grandmultiparas woman was defined as a woman who gave birth to 5 and more deliveries after 24 weeks gestations [5]. A total of 8040 deliveries was performed during the year, of these 430 were grandmultiparas which were the actual number of grandmultiparity during the whole year. They were matched to 657 multiparas (parity 1-4) women who delivered during the same time scale.

Sociodemographic factors, obstetric complications, and neonatal morbidity for both groups were recorded from the case note. Maternal variables we assessed included diabetes mellitus, hypertensive disorders of pregnancy, premature rupture membrane, placental abruption, placenta previa, medical problems (such as asthma, epilepsy and hypothyroidism), postpartum hemorrhage, tears, cesarean hysterectomy, preterm labor, mode of delivery and post term labor (diabetes was assessed separately because it is important variable for pregnancy outcomes). Each of these variables was analyzed against each group. For clarity, medical problems included (asthma, epilepsy and hypothyroidism) and diabetes included both pre-existing and gestational diabetes. Macrosomia is defined as fetal weight greater or equal to 4kg.

Fetal variables we assessed were Admission to nursery, small for gestational age, fetal death, Apgar score, fetal weight, gestational age at delivery, fetal distress and macrosomia. Each of the fetal complications was assessed against each group. This study was approved by the Ethics Committee of the College of Medicine of Qassim University.

#### Statistical analysis

The Statistical Package for the Social Sciences (SPSS 17 for Windows) was used for recording and statistical analyses of data. The descriptive statistics used included the mean, the frequency distribution and the standard deviation. A chi-square test was used to compare the means of qualitative data, whereas a Student's t-test was used to compare the means of quantitative data. In multivariate analysis, all independent variables were added to the model at the same time. The results of the analysis are presented as odds ratio (OR) and 95% confidence interval (95% CI). The test of significant was set at a  $p < .05$ .

### 3. RESULTS

The total number of deliveries during the study period was 8040, of these 430 were grandmultiparas. Thus, the prevalence of grandmultiparity was 5.3%. Of 430, grandmultiparas, 28.6% (123) were below 35 years of age (younger grandmultiparas), in this group the CSR was 27.2% (72). There was no significant differences in the CS rate when they were compared with those above 35 years of age 72.8% (307)  $p = 0.666$  as show in table 1.

Table 2 shows the frequency of the individual parity and the associated percentage.

In this study, the distribution of age according to parity showed a linear relationship with good agreement with p-p plot distribution. There were significant differences in maternal age ( $28.8828 \pm 5.26145$  vs.  $36.8488 \pm 4.40522$ ;  $p < 0.001$ ), number of previous abortions ( $.3181 \pm .60298$  vs.  $.8279 \pm 1.05916$ ;  $P < .001$ ), gestational age at delivery ( $38.4556 \pm 1.75031$  vs.  $38.0695 \pm 2.00399$ ;  $P = 0.001$ ) and the number of parity ( $2.2907 \pm 1.22442$  vs.  $6.3349 \pm 1.52353$ ;  $P < 0.001$ ) between the study and the control groups. Fetal weight was similar between the two groups ( $p = .751$ ).

Chi-square test was used to explore the differences in the antenatal complication between the multiparas and the grandmultiparas women. For clarity, PIH includes both preeclampsia and superimposed hypertension. Medical disorders reported include (bronchial asthma

| Age         | Multiparas (n=657) | Grandmultiparas (n=430) | p-value |

**Table 3.** Comparison of antenatal complications between multiparas and grandmultiparas. Values are presented as number (percentage)

which constituted the majority, hypothyroidism and epilepsy). As listed in table 3, grandmultipara women had a higher frequency for medical disorders ( $p = 0.009$ ), but both groups did not differ significantly in other antenatal obstetrics complications ( $p > 0.05$ ).

Chi-Square test and Fisher's exact test (cell count less than 5) were used to examine the differences between some post partum obstetrical complications between multiparas and grandmultiparas. Grandmultiparas when compared to multiparous women they were at an increased risk of cesarean delivery ( $P < .001$ ). On the other hand, multiparous women compared to grandmultiparas were more likely to deliver by ventouse ( $p = 0.0062$ ). Other postpartum complications did not differ significantly between the two groups ( $p > 0.05$ ), table 4.

Binary logistic regression was used to explore the association of some selected antenatal and postnatal variables between multiparas and grandmultiparas as presented

| Characteristics               | Multiparas (n=657) | Grandmultiparas (n=430) | P-value |
|-------------------------------|--------------------|-------------------------|---------|
| Postpartum hemorrhage         | 5(0.8)             | 5(1.2)                  | 0.529   |

| Intensive care unit admission | 1*             | .790            | .420-1.486  | .465 |

**Table 5.** Odds ratio and 95% confidence interval for grandmultiparity and some selected pregnancy outcomes. 1\* reference category. Abbreviations: OR, odds ratio; CI confident interval

in table 5. Grandmultiparas were significantly associated with increased incidence of cesarean section (OR=2.699, CI=2.072-3.515, p<0.001), macrosomic babies (OR=1.675; 95% CI=1.004-

2.796, p=.048), diabetes mellitus (OR=1.634, 95%CI=1.076-2.481, .021) and PIH (OR=1.838, 95% CI=1.054-3.204, p= .032). Logistic regression analyses demonstrated that grandmultiparas were not significantly associated with increased risk of hypertensive disorders, PROM, preterm delivery, IUFD, abruption, postpartum hemorrhage and IUGR.

#### 4. DISCUSSION

The incidence of grandmutiparity in the current study was 5.3 %. Due to the lack of consensus on the definition of grandmultiparity, previous regional studies from Saudi Arabia have documented different incidence of grandmultiparity [1, 6]. Higher prevalence of grandmultiparity was reported in developing countries [7, 8]. The low

prevalence rate of grandmutiparity in this study can be explained by the high acceptance of family planning. Jabbar et al. in their study, which included 2675 Saudi women attending a gynecology out- patient, demonstrated that 56.0% of women were using some form of contraceptive [9].

Of the 430 grandmultiparas in this study, 123(28.6) were less 35 years of age, which indicate early age of marriage leading to the concept of “younger grandmultiparity” and which may constitute additional risk for further complications. There was no significant difference in the rate of CS between grandmutiparity age less than 35 years compared to those greater than 35 years of age (60.0% vs. 62.3%l p= 0.666).

In the current study, we found that there was a significant association between grandmultiparity and adverse pregnancy outcomes (such as cesarean delivery, fetal macrosomia, Diabetes mellitus and pregnancy induced hypertension). These findings contradict with previous findings, [10, 11, 12, 13] which concluded that grandmutiparity is not associated with increased risk for adverse pregnancy outcomes. Certainly, our data support previous published findings [14, 15,16, 17] which stated that grandmutiparity continue to constitute potential risks for adverse pregnancy outcomes even after controlling for confounders.

The high rate of CS among grandmutliparas women in this study can be explained by high frequency of fetal macrosomia, diabetes mellitus and pregnancy induced hypertension (p<0.05). All of these complications of pregnancy are well documented to increase the rate of cesarean delivery. This data showed, that within grandmultiparity, 120(27.9%) of grandmultiparas were less than 35 years of age, of whom 72(60%) were delivered by CS with no significant differences compared to those greater than 35 years of age, (p=0.666). This indicates that, this group of women started their reproduction before pelvic maturity and consequently resulted in high rate of CS due to fet-to-pelvic disproportion. while the high rate of CS among old grandmutiparas, may be due to secondary contracted pelvic as a result of repeated compensatory lordosis of pregnancy [18].

This study revealed that there was no significant association between grandmultiparity and placenta abruption, placenta previa, preterm labor, postpartum hemorrhage and babies admission to the intensive care unit (ICU), p>0.05. This agreed with other findings. Nassar and colleagues observed no significant differences in antepartum hemorrhage, intrauterine growth restriction and stillbirth rates [8, 19]. However, Rayamajhi et al., reported stronger association of hypertensive disorders in pregnancy, preterm birth, anemia, postpartum hemorrhage in the grandmulmultiparity [20].

In his study, 3 (.7%) cases of grandmultiparity underwent hysterectomies, one for complete placenta previa and two for uncontrolled postpartum hemorrhage, giving a hospital incidence of one in 2680 deliveries, a comparable incidence of one in 2581 was reported from Tunisia [21]. No maternal death was reported in this report.

In the current study, there was no significant association between grandmultipara and admission to ICU, intrauterine fetal death and low birth weight babies.

The shortcomings of this study are its retrospective nature and the gathering of data from a single center rather than multicenter (the latter of which could be more representative of the population).

## 5. CONCLUSION

In view of the results obtained in this study, we feel that grandmultiparity continue to pose additional risk for pregnancy outcomes even in modern obstetrics care. In a community where large family is desirable, still there is a place for family planning. Again, conduction of good antenatal and intrapartum care will result in much reduction of these adverse outcomes for both fetus and mother. Further study is warranted to investigate the outcome of younger grandmultiparity.

**CONFLICT OF INTEREST: NONE DECLARED.**
