Abstract

Objective: Many prediction models for Coronavirus Disease 2019 (COVID-19) have been developed. External validation is mandatory before implementation in the Intensive Care Unit (ICU). We selected and validated prognostic models in the Euregio Intensive Care COVID (EICC) cohort.

Study Design and Setting: In this multinational cohort study, routine data from COVID-19 patients admitted to ICUs within the Euregio Meuse-Rhine were collected from March to August 2020. COVID-19 models were selected based on model type, predictors, outcomes, and reporting. Furthermore, general ICU scores were assessed. Discrimination was assessed by area under the receiver operating characteristic curves (AUCs) and calibration by calibration-in-the-large and calibration plots. A random-effects meta-analysis was used to pool results.

Results: 551 patients were admitted. Mean age was 65.4±11.2 years, 29% were female, and ICU mortality was 36%. Nine out of 238 published models were externally validated. Pooled AUCs were between 0.53 and 0.70 and calibration-in-the-large between -9% and 6%. Calibration plots showed generally poor but, for the 4C Mortality score and SEIMC score, moderate calibration.

Conclusion: Of the nine prognostic models that were externally validated in the EICC cohort, only two showed reasonable discrimination and moderate calibration. For future pandemics, better models based on routine data are needed to support admission decision-making.

Running title: Predicting COVID-19 prognosis in the ICU remains challenging: external validation in a multinational regional cohort

1 Introduction

During the Coronavirus Disease 2019 (COVID-19) pandemic, many prediction models were developed for diagnostic and prognostic purposes. The accurate prediction was paramount to support clinical decision-making, particularly during the early phase of the pandemic when little was known about the manifestations of the disease caused by the new Severe Acute Respiratory Syndrome Coronavirus 2 (SARS-CoV-2). Furthermore, prediction of patient outcome can improve effective management of bed availability in times of a pandemic where knowledge and capacity are under pressure. This was especially the case in the Intensive Care Unit (ICU), as many patients with severe SARS-CoV-2 infection required organ support there [1, 2].

A prediction model needs to meet several criteria to be useful in daily clinical practice. In the third update of the living systematic review by Wynants et al. [3], 238 prediction models for prognosis and diagnosis in COVID-19 have been identified and assessed for risk of bias. The risk of bias of all included models was evaluated as being high or, at best, unclear. For a model to perform well, both discrimination and calibration are important. In addition, model predictors must be routinely available. Furthermore, models need to be applicable to the population and settings requiring prediction, such as prognosis in the ICU, particularly during scarce bed availability. However, external validation of prediction models, which means testing the model in another sample of patients than it has been developed in, is often omitted, particularly in the ICU [4]. External validation is essential to generalise results to future patients and should precede the implementation of models in daily clinical practice [5, 6]. Several external validation studies of prediction models for COVID-19 patients have been conducted. However, these studies focused mostly on patients admitted to the hospital ward instead of the ICU [7-

9]. There is still a lack of ICU-specific prediction models, and applicability of general models to the ICU population is likely possible for some models only [3, 10].

Therefore, we aimed to evaluate the predictive performance of published prediction models by selecting promising prognostic prediction models with clinically available predictors for external validation in our multinational COVID-19 cohort consisting of patients admitted to the ICUs within the Euregio Meuse-Rhine. As the majority of the 238 evaluated prediction models were developed at the beginning of the pandemic, we used data from the first pandemic wave for external validation.

2 Materials and Methods

The paper is reported according to the TRIPOD clustered data reporting guideline [11-14]. Every section of the Materials and Methods is detailed in the Appendix A.2.

2.1 Model selection

Prognostic prediction models for COVID-19 patients in the ICU were identified and extracted from https://www.covprecise.org/, the international Precise Risk Estimation to optimise COVID-19 Care for Infected or Suspected patients in diverse settings (COVID-PRECISE) group, in collaboration with the Cochrane Prognosis Methods Group according to the living systematic review of Wynants et al. (Figure 1) [3]. Inclusion and exclusion criteria are described in the Appendix A.2.1 and the selection process is shown in Figure 1.

2.2 External validation cohort

All patients with PCR and/or chest CT scan confirmed COVID-19 and respiratory failure admitted to ICUs of any of the seven participating Euregio hospitals were consecutively included between March 2nd and August 12th, 2020 (Figure 2) [15]. Hence the study sample size was determined pragmatically. An extensive description of our methods and cohort has been described in the Appendix A.2.2 and elsewhere [16, 17].

2.3 Predictors

Using a predefined study protocol [16, 17], predictor data up to 24 hours of ICU admission were acquired from electronic medical records and manually or electronically collected depending on the centre. The collected variables used as predictors and outcomes are described in A.2.3 and Table A.1 of the Appendix [18]. Unknown, inappropriate, and

inapplicable data were considered missing at random since missingness of data were related to other variables in the dataset and unlikely to be related to the true value itself [19-21].

2.4 Outcomes

Follow-up ended when patients were either discharged from the ICU or died in the ICU and was determined as ICU discharge or death. Patients whose outcome status after transportation could not be retrieved after re-contacting the hospital were censored (Appendix A.2.4). Sensitivity analyses were performed without censored patients.

2.5 Description of included prediction models

The study characteristics of included prediction models and risk of bias are described in more detail in the Appendix A.2.5 [22-24]. The risk of bias of the individual studies was scored by Wynants et al. [3] using the Prediction model study Risk Of Bias Assessment Tool (PROBAST) [25].

2.6 Ethics approval

Ethical approval was obtained from the medical ethics committee (Medisch Ethische Toetsingscommissie 2020-1565/3 00 523) of Maastricht UMC+.

2.7 Statistical analyses

IBM SPSS Statistics version 25 (IBM corporation, NY, USA) and R version 4.0.4 were used for all analyses. Microsoft PowerPoint version 16.59 was used to create figures. Data are presented as mean ± SD, median [IQR], or percentages. Descriptive statistics were performed for the whole cohort as well as for the individual Euregio countries. We included all patients in the

analyses. In addition, sensitivity analyses were performed without censored transferred patients who, in the main analysis, contribute to the survived group. Missing data were imputed using multiple imputation if <50% of values on a variable were missing. Variables with more missings were omitted from the analysis. The number of imputations was based on the percentage of patients with missing data [26]. Continuous and categorical predictors were appropriately handled using the same definitions and cut-off values as the development study. The prognostic index (PI) was calculated for each patient by the sum of the models' regression coefficients, reported in the development studies, multiplied by the individual patient values. The PI was transformed into a probability score when a model intercept was reported. For the Sequential Organ Failure Assessment (SOFA) score and the Acute Physiology And Chronic Health Evaluation II (APACHE II) score, risk scores instead of separate variables were already available for all patients and therefore directly assessed. The performance of the models was assessed by both discrimination and calibration measures. Model discrimination, the ability to separate patients who died in the ICU and those who are discharged, was determined as the area under the receiver operating characteristic (ROC) curve (AUC). An AUC of 0.5 implies inability to distinguish between those who die in the ICU and those who are discharged, whereas one means perfect discrimination. Model calibration refers to the agreement between observed risk and the predicted risk [27, 28]. Calibration was assessed by calibration-in-the-large (i.e., the difference between the predicted and observed probability of mortality) and by visual inspection of the calibration plot. Calibration could only be assessed in models that reported an intercept to calculate a probability instead of a unitless risk score only. The cohort was divided into deciles according to the estimated probability score, displayed by points in the calibration plot. Perfect calibration is shown by the diagonal reference line, indicating agreement between predicted and observed probabilities over the range of

predictions. Dots located above the reference line indicate underestimation by the model, while overestimation is reflected by the points below the reference line. Pooled AUCs and calibration-in-the-large were calculated for the three Euregio country parts using random-effects meta-analysis and 95% confidence intervals were computed [12, 13].

3 Results

3.1 Model selection

A total of 238 prediction models for COVID-19 were identified by COVID-PRECISE. Firstly, 129 models were excluded because they were diagnostic or not applicable to the ICU population (Figure 1). Subsequently, 45 models were excluded due to unusable outcome measures such as ICU admission or severe COVID-19 pneumonia. Forty-three models were excluded as full information on predictors, intercepts, and coefficients was not present in the original article or supplement. Of the 21 potential prognostic models, three were not applicable since some predictors were not relevant for the ICU (e.g., cough, fatigue), four models included predictors that were not routinely available in Euregio ICUs (e.g., interleukin 6 or pro-calcitonin), and seven were excluded because it contained predictors that were more than 50% missing in our cohort. The APACHE II model [29] is widely used in the ICU and was added as prognostic model. The SOFA and CURB-65 score, models that are also broadly implemented, were already included in the models selected via COVID-PRECISE. Furthermore, the Spanish Society of Infectious Diseases and Clinical Microbiology (SEIMC) score [30], which applied to the Euregio Intensive Care COVID (EICC) cohort, but was not available in COVID-PRECISE, was investigated. Thus, nine potential prognostic prediction models were selected for external validation. One model had an unclear risk of bias, five had a high risk of bias, and three models comprised already established prediction scores (Figure 1 and Table 1).

3.2 External validation cohort

From March 2nd to August 12th, 2020, 551 patients with COVID-19 pneumonia were admitted to seven ICUs across the Netherlands, Belgium, and Germany (Figure 2). Demographic and clinical characteristics and outcome measures are reported in Table 2 for the full EICC cohort

and in Table A.2 (Appendix) for the individual country parts. Mean age of the cohort was 65.4 ± 11.2 years, the mean body mass index was 29.0 ± 5.3 kg/m^2, and 29% were female. At ICU admission, disease severity, as defined by APACHE II and SOFA scores, was 16.1 ± 5.5 and 6.2 ± 3.0.

3.3 Predictors

In our dataset, 309 (56%) of the patients had at least one missing value on any of the variables from the full set of predictors. Therefore, the number of imputations of the multiple imputation model was set to 56.

3.4 Outcomes

The ICU mortality rate was 36%, and the median [IQR] length of stay was 15.2 [6.0-29.9] days (Table 2). From 27 (5%) transported patients, survival status could not be retrieved after re-contacting individual hospitals and was therefore censored.

3.5 Model performance

3.5.1 Unclear risk of bias prognostic model for COVID-19

The 4C Mortality score [22] had a pooled AUC of 0.70 (95% CI 0.64-0.76) for the full cohort (Table 3). Pooled calibration-in-the-large was -1% (95% CI -19-17%) (Table 3). The calibration plot is shown in Figure 3. Sensitivity analyses (Table A.3 and Figure A.1, Appendix) and country-specific analyses (Table A.4, Appendix) showed highly comparable discrimination. Calibration-in-the-large, however, varied between the three Euregio country parts (Table A.4, Appendix).

158 3.5.2 High risk of bias prognostic models for COVID-19

159 The DL-death and DCSL-death model [23] had a pooled AUC of 0.53 (95% CI 0.43-0.64) and
160 0.53 (95% CI 0.42-0.63), respectively. The pooled AUC of the Clinical model [24] was 0.70 (95%
161 CI 0.65-0.74), the Mechanistic COVID-19 lethality score [31] 0.67 (95% CI 0.62-0.72), and the
162 SEIMC [30] 0.70 (95% CI 0.65-0.74) (Table 3).

163

164 Pooled calibration-in-the-large were -2% (95% CI -14-10%) for the DL-death model, 6% (95% CI
165 -6-18%) for the DCSL-death model, and -5% (95% CI -20-11%) for the SEIMC model (Table 3).
166 Figure 3 shows calibration plots for the DL-death, DCSL-death, and SEIMC models. Similar
167 results were observed in sensitivity analyses (Table A.3 and Figure A.1, Appendix). Minor
168 differences in model discrimination existed between the three Euregio country parts, with the
169 DL-death and DCSL-death having the lowest AUC in the Belgian part, whereas for the Clinical
170 model, Mechanistic COVID-19 mortality score and SEIMC lowest AUCs were observed in the
171 German part (Table A.4, Appendix). Calibration-in-the-large, however, varied largely between
172 the individual countries (Table A.4, Appendix).

173

174 3.5.3 Established prognostic models to predict mortality for acute respiratory illness and ICU
175 patients

176 The pooled AUC was 0.68 (95% CI 0.64-0.73) for the CURB-65 score [32], 0.65 (95% CI 0.60-
177 0.69) for the APACHE II score [29], and 0.62 (95% CI 0.56-0.68) for the SOFA score [33] (Table
178 3).

179 Pooled calibration-in-the-large was -9% (95% CI -21-3%) for the APACHE II score, and the
180 calibration plot is shown in Figure 3. Similar model performance was observed in sensitivity
181 analyses (Table A.3 and Figure A.1, Appendix). However, the German part had a lower AUC

than the Belgian and Dutch Euregio parts, whereas calibration-in-the-large was best in the Belgian part (Table A.4, Appendix).

4 Discussion

In this study, we reviewed 238 prognostic prediction models for COVID-19 and externally validated nine using routinely available data in a multinational cohort of COVID-19 patients admitted to seven ICUs in Belgium, the Netherlands, and Germany during the first pandemic wave. In addition, established ICU prediction models were added for external validation in COVID-19 patients. Most studied models, among which prediction models for COVID-19 rated as high risk of bias and established ICU scores, revealed poor performance regarding both discrimination and calibration. However, the 4C Mortality score and SEIMC showed reasonable model performance after external validation in an ICU cohort. Taken together, this shows that, despite the huge effort to develop many models early in the pandemic, their clinical value to support decision-making is, overall, poor. This highlights that data infrastructure for high-quality studies on model development, external validation, and implementation are required to improve data-driven decision support in future pandemics [34].

A direct comparison of model performance is hampered as case-mix differences exist between the model development population and the EICC cohort. These case-mix differences as well as possible explanations for the observed model performance, are extensively described in A.4 of the Appendix. Except for the APACHE II score and SOFA score, the included models were developed and/or validated in hospitalised patients or outpatients, with none of them or only a small subset of the cohort being admitted to the ICU. All patients included in the EICC cohort, on the contrary, were admitted to the ICU, indicating more severe illness and/or advanced disease course. Furthermore, in the ICU, patient selection likely played a role as patients with a high age and burden of comorbidities were often excluded from ICU admission. The EICC cohort reflects a case-mix with a relatively homogeneous population compared to model

development studies on the hospital ward or general population, as patients at highest risk, who are not accepted for ICU admission, and lowest risk, not requiring intensive organ support were likely not included. However, considerable heterogeneity was observed in the EICC cohort [16], also illustrated by differences in model performance between the Euregio country parts. Since the discriminatory performance depends on case-mix variability, models developed or validated in hospitalised or outpatient populations showed lower AUCs after external validation in our relatively homogeneous ICU cohort [27, 28]. Previous validation studies evaluating prediction models in other cohorts often included general populations, explaining why higher AUCs are observed compared to the EICC cohort. Therefore, it is inappropriate to directly compare AUC from validation studies in a general population to the ICU population. Nevertheless, high-quality prediction models could support a multifactorial decision when stress on ICU bed availability increases during a pandemic, particularly when driven by an intervening national healthcare policy [16, 35].

4.1 Limitations

We evaluated nine prognostic models, including only one model at unclear risk of bias, five models at high risk of bias, and three established models with moderate to poor performance, which indicates that there is still a lack of well-performing and valid prediction models for the ICU population. However, we could not evaluate all high risk of bias prediction models as data on certain variables were missing, excluding these prediction models. Our analyses cannot provide evidence that other high risk of bias models should be discouraged, although as a proof of concept, our study may warrant caution, at the very least. Furthermore, we externally validated the APACHE II score instead of the more recent and advanced APACHE IV score [36] as data for the APACHE II score were more complete. Another limitation was the lack of

information after transport to another ICU for 25 patients. However, we performed sensitivity analyses without these patients that showed comparable results. In addition, the original article of certain models did not report an intercept, and calibration could therefore not be assessed. The included COVID-19 prediction models were developed in the early phase of the pandemic and externally validated using patient data from the first pandemic wave. The dynamic development of the virus was not considered and, therefore, our results could not be generalised to ICU patients admitted later in the pandemic and suffering from other SARS-CoV-2 variants. However, first pandemic wave data were used, since the stress on healthcare systems and the accompanying need for prediction was highest during that period. As considerable heterogeneity is observed between SARS-CoV-2 variants and pandemic waves, models should be externally validated or updated in other pandemic wave cohorts [37, 38]. Model updating and extension could further improve model performance which has not been performed yet [27, 28]. Our study, therefore, sets the stage for model updating and extension of the promising 4C Mortality score and SEIMC model.

5 Conclusions

In this study, nine out of 238 available COVID-19 prognostic models were externally validated in the EICC cohort based on routinely collected data. Only two of these nine models, the 4C Mortality score and the SEIMC, showed reasonable discrimination and moderate calibration. For future pandemics, better prediction models based on routine data are essential to improve data-driven decision support. Therefore, infrastructure for high-quality studies on model development and external validation are required.

253 Table 1 Model characteristics of included prognostic prediction models

Study	Model	Derivation and validation cohort	Setting development study	Patients/disease	Year, country	Predictors	Outcome
Unclear risk of bias prognostic model for COVID-19							
Knight et al. [22]	4C Mortality score	n = 35,463 (derivation) n = 22,361 (validation)	General hospital ward	Adults with COVID-19	2020, England, Scotland, and Wales	Age, sex, number of comorbidities, respiratory rate, peripheral oxygen saturation, Glasgow coma scale, urea, CRP	Mortality
High risk of bias prognostic models for COVID-19							
Zhang et al. [23]	DL-death	n = 775 (derivation) n = 226 (validation)	General hospital ward	Adults with RT-PCR confirmed COVID-19	2020, China and the United Kingdom	Age, sex, neutrophil count, lymphocyte count, platelet count, CRP, creatinine	Mortality (and poor outcome)[a]

Zhang et al. [23]	DCSL-death	n = 775 (derivation) n = 226 (validation)	General hospital ward	Adults with RT-PCR confirmed COVID-19	2020, China and the United Kingdom	Age, sex, chronic lung disease, diabetes mellitus, malignancy, cough, dyspnea, neutrophil count, lymphocyte count, platelet count, CRP, creatinine	Mortality (and poor outcome)[a]
Wang et al. [24]	Clinical model	n = 286 (derivation) n = 44 (validation)	General hospital ward	RT-PCR/genetic testing confirmed, and imaging suspected COVID-19 cases	2020, China	Age, history of hypertension, history of coronary heart disease	Mortality
Bello-Chavolla et al. [31]	Mechanistic COVID-19 lethality score	n = 41,307 (derivation) n = 10,326 (validation)	Outpatients and general hospital ward	Suspected, confirmed and negative COVID-19 cases	2020, Mexico	Age, diabetes, diabetes*age, obesity, pneumonia, chronic kidney disease, chronic obstructive pulmonary disease, immunosuppression	Mortality

Berenguer et al. [30]	SEIMC	n = 3358 (derivation) n = 1269 (validation)	General hospital ward	RT-PCR confirmed COVID-19 cases	2020, Spain	Age, low age-adjusted SaO_2, neutrophil-to-lymphocyte ratio, eGFR (CKD-EPI), dyspnea, sex	Mortality
Established prognostic models							
Lim et al. [32]	CURB-65 score	n = 718 (derivation) n = 214 (validation)	General hospital ward	CAP patients	2003, United Kingdom, New Zealand, and the Netherlands	Confusion, urea, respiratory rate, systolic or diastolic blood pressure[b], age	Mortality
Knaus et al. [29]	APACHE II score	n = 5815 (validation)	ICU	Patients admitted to ICU	1985, United States	Age, history of severe organ failure or immunocompromise, temperature, mean arterial	Mortality

						pressure, pH, heart rate or pulse, respiratory rate, sodium, potassium, creatinine, acute kidney failure, hematocrit, white blood cell count, Glasgow coma scale, FiO_2	
Vincent et al. [33]	SOFA score	n = 1643 (derivation)	ICU	ICU patients (without short stay and postoperative patients)	1996, Europe and the United States	PaO_2/FiO_2, platelets, Glasgow coma scale, bilirubin, mean arterial pressure or vasoactive agents, creatinine	Mortality

ICU, intensive care unit; COVID-19, Coronavirus disease 2019; RT-PCR, reverse transcription-polymerase chain reaction; CAP, community-acquired pneumonia; CRP, C-reactive protein; eGFR, estimated glomerular filtration rate; FiO_2, Fraction of Inspired Oxygen; PaO_2/FiO_2 ratio, the ratio of partial pressure of oxygen in arterial blood divided by the fraction of inspired oxygen.

a. We only included models having mortality as outcome.

b. One point was scored if systolic blood pressure was < 90 mmHg or diastolic BP was ≤ 60 mmHg.

260 Table 2 Characteristics for the full Euregio Intensive Care COVID cohort

Characteristics	Full cohort n = 551

- Other ICU, n (%)	90 (16)
Glasgow coma scale at admission	14.7 ± 1.1
Respiratory rate at admission, /min	24.6 ± 7.1
SpO_2 at admission, %	91.4 ± 6.8
pH at admission	7.4 ± 0.1
Lowest PaO_2/FiO_2 ratio at admission	15.4 ± 10.6
Highest FiO_2 at admission, %	71.2 ± 21.5
Lowest MAP at admission, mmHg	68.5 ± 18.8
Heart rate at admission, bpm	93.1 ± 18.9
Vasopressor use at admission, %	360 (65)
Creatinine at admission, µmol/l	101.2 ± 82.4
Urea at admission, mmol/l	11.6 ± 11.1
Dialysis at admission, n (%)	37 (7)
Bilirubin at admission, µg/l	10.0 ± 8.6
Thrombocytes at admission, $*10^9$/l	248.7 ± 105.7
Temperature at admission, º Celsius	37.6 ± 1.2
CRP at admission, mg/l	184.8 ± 98.0
Neutrophils at admission, $*10^9$/l	8.3 ± 6.0
Lymphocytes at admission, $*10^9$/l	0.89 ± 11.6
Invasive mechanical ventilation during ICU stay, n (%)	434 (79)
Reintubation, n (%)	44 (8)

Duration of invasive mechanical ventilation, days	11.4 [2.3 – 23.0]
Mechanical circulatory support, n (%)	32 (6)
Kidney replacement therapy, n (%)	112 (20)
ICU mortality, n (%)	196 (36)
Length of ICU stay, days	15.2 [6.0 – 29.9]

Data are presented as mean ± SD, median [IQR], or percentages. HIV, human immunodeficiency virus; APACHE II, Acute Physiology And Chronic Health Evaluation II; SOFA, Sequential Organ Failure Assessment; ICU, Intensive Care Unit; SpO_2, peripheral capillary oxygen saturation; PaO_2/FiO_2 ratio, the ratio of partial pressure of oxygen in arterial blood divided by the fraction of inspired oxygen; FiO_2, the fraction of inspired oxygen; MAP, mean arterial pressure; CRP, C-reactive protein.

268 Table 3 External validation of prognostic prediction models in the Euregio Intensive Care COVID
269 cohort

Study	Model	Discrimination[a]	Calibration-in-the large[b]
Unclear risk of bias prognostic model for COVID-19			
Knight et al. [22]	4C Mortality score	0.70 (95% CI 0.64-0.76)	-1% (95% CI -19-17%)
High risk of bias prognostic models for COVID-19			
Zhang et al. [23]	DL-death	0.53 (95% CI 0.43-0.64)	-2% (95% CI -14-10%)
Zhang et al. [23]	DCSL-death	0.53 (95% CI 0.42-0.63)	6% (95% CI -6-18%)
Wang et al. [24]	Clinical model	0.70 (95% CI 0.65-0.74)	-[c]
Bello-Chavolla et al. [31]	Mechanistic COVID-19 lethality score	0.67 (95% CI 0.62-0.72)	-[c]
Berenguer et al. [30]	SEIMC	0.70 (95% CI 0.65-0.74)	-5% (95% CI -20-11%)
Established prognostic models			
Lim et al. [32]	CURB-65 score	0.68 (95% CI 0.64-0.73)	-[c]
Knaus et al. [29]	APACHE II score	0.65 (95% CI 0.60-0.69)	-9% (95% CI -21-3%)
Vincent et al. [33]	SOFA score	0.62 (95% CI 0.56-0.68)	-[c]

270

271 a. Discrimination is reported as the pooled area under the ROC curve with 95% CI for all 56
272 imputed sets using random-effects meta-analysis.

b. Calibration-in-the-large is reported as the pooled difference between the predicted and observed mortality risk with 95% CI for all 56 imputed sets using random-effects meta-analysis. Positive values suggest overestimation, whereas negative values suggest underestimation.

c. Intercept not reported or risk score.

277 Figure 1 Flowchart identifying prediction models

278

279

280

281

282

283

284 COVID-19, Coronavirus Disease 2019; ICU, intensive care unit; ARDS, Acute respiratory distress
285 syndrome; ASAT, aspartate aminotransferase. Legend: models for diagnosis and identifying people at
286 risk in the general population were excluded. The remaining models were mainly prognostic, and
287 further selection was based on outcome measures. As our cohort was composed of ICU patients only,
288 in whom severe COVID-19 infection can be assumed, the outcome ICU admission, as well as
289 progression to severe COVID-19, severe COVID-19, and ARDS, were excluded. Outcome measures
290 length of hospital stay, in-hospital mortality, and in- or out of hospital mortality were used. Since
291 reporting of predictors and coefficients are necessary in order to validate prediction models as
292 specifically assessed in step 4.9 in PROBAST (12), a tool to assess the risk of bias and applicability of
293 prediction model studies, models which did not report or probably did not report this, or were
294 machine learning or artificial intelligence studies, were excluded. Finally, predictors included in one of
295 the final 21 prediction models were evaluated. Again, as we only included ICU patients and our goal
296 was to validate models containing routinely available data, models including symptoms not relevant
297 for ICU patients, not routinely available data, or data that were not available in the EICC cohort (e.g.,
298 ≥50% missing data) were excluded. Additionally, two promising models, which were not available in
299 the COVID-PRECISE, were added.

Figure 2 Flowchart Euregio Intensive Care COVID cohort [16]

Figure 3 Calibration plots prediction models

The cohort was divided into deciles according to the estimated probability score, displayed by points in the calibration plot.

Declarations

Declarations of interest

None.

Informed consent

Informed consent was waived by the METC of Maastricht UMC+. However, each of the participating hospitals had its own policy and approach. For example, in Maastricht UMC+, the board of directors adopted a policy to inform patients and ask their consent to use collected data. Our manuscript does not contain individual person's data. Therefore, consent to publish does not apply.

Data availability

The datasets generated and/or analysed during the current study are not publicly available due to data-sharing agreements of the participating hospitals. Individual patient data and the pseudo-anonymised dataset will not be made available to others.

Author contributions

All authors contributed substantially to this study. Conceptualisation and study design: SMJvK, LW, BS, JM-S, AH, CIES, JB, LJMS, ICCvdH, GM, DM, BCTvB. Methodology: DAMM, SMJvK, LW, LJMS, ICCvdH, BCTvB. Software: DAMM, SMJvK, LW, LJMS, ICCvdH, BCTvB. Validation: DAMM, BCTvB. Formal analysis: DAMM, SMJvK, LW, LJMS, ICCvdH, BCTvB. Investigation: DAMM, BS, JM-S, AH, CIES, JB, DM, BCTvB. Resources: DAMM, SMJvK, LW, BS, JM-S, AH, CIES, DCJJB, JB, MvL, LJMS, ICCvdH, GM, DM, BCTvB, CoDaP investigators. Data curation: DAMM, SMJvK, LW, LJMS, BCTvB, CoDaP investigators. Writing – original draft: DAMM, ICCvdH, BCTvB. Writing –

review & editing: DAMM, SMJvK, LW, BS, JM-S, AH, CIES, DCJJB, JB, MvL, LJMS, ICCvdH, GM, DM, BCTvB, CoDaP investigators. Visualisation: DAMM, SMJvK, LW, LJMS, ICCvdH, BCTvB. Supervision: DAMM, ICCvdH, BCTvB. Project administration: DAMM, BCTvB. Funding acquisition: BS, ICCvdH, GM, DM, BCTvB.

Funding

This work was supported by the "Interreg Euregio Meuse-Rhine" [Covid Data Platform (CoDaP) grant: Interreg-EMR 187]. The funding source was not involved in the study design, data collection, data analysis, data interpretation, writing process, and decision to submit for publication.

238 COVID-19 prediction models
Model type
129 models excluded:
• 11 identify people at risk in the general population
• 118 diagnostic
109 models
Outcome measures
45 models excluded:
• 6 ICU admission
• 23 progression to severe COVID-19
• 10 severe COVID-19
• 6 ARDS
64 models
Predictors and/or coefficients reported
43 models excluded:
• 2 no
• 4 probably no
• 27 no information
• 10 not applicable
21 models
Model predictors
14 models excluded:
• 3 symptoms not relevant for ICU (e.g., fatigue)
• 4 not routinely available markers (e.g., procalcitonin)
• 7 predictor not available in our cohort (e.g., ASAT)
7 models
2 models included:
• APACHE II score
• SEIMC score
9 models

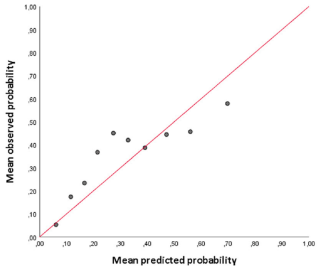
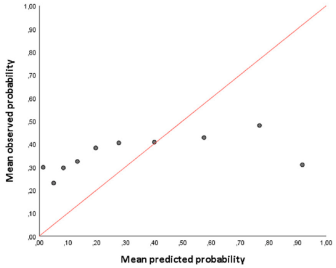
Unclear risk of bias prognostic model for COVID-19

Knight et al. 4C Mortality score [22]

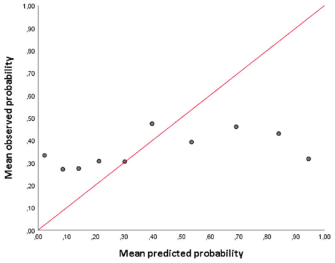


High risk of bias prognostic models for COVID-19

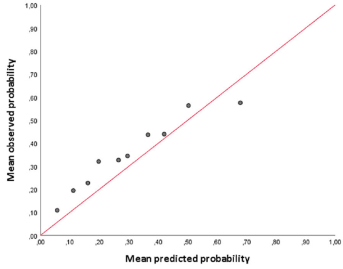
Zhang et al. DL-death [23]



Zhang et al. DCSL-death [23]

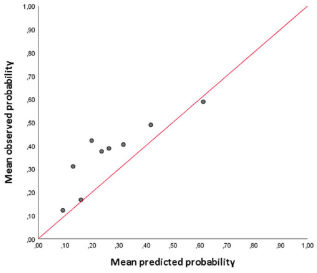


Berenguer et al. SEIMC [16]



Established prognostic models

Knaus et al. APACHE II [15]



The cohort was divided into deciles according to the estimated probability score, displayed by points in the calibration plot.

What is new

- External validation of prediction models is often omitted in the ICU
- Of 238 reviewed prognostic prediction models, 9 were externally validated
- Only 2 out of 9 models showed reasonable discrimination and moderate calibration
- Better prediction models based are needed to support admission decision-making
