

Determinants of Susceptibility and Resistance to Feline Leukemia Virus Infection. I. Role of Macrophages^{1, 2, 3}

Edward A. Hoover,^{4, 5} Jennifer L. Rojko,⁴ Pamela L. Wilson,⁴ and Richard G. Olsen^{4, 5, 6}

ABSTRACT—The role of autochthonous peritoneal feline macrophages (M θ) in the age-related resistance of cats to feline leukemia virus (FeLV) was investigated by a study of the functional properties and FeLV susceptibility of M θ from kittens and adult cats and the effect of hydrocortisone (HC) and silica on M θ -FeLV interactions. Although the phagocytic functions of isolated M θ from kittens and adults were equivalent, the mean FeLV susceptibility of M θ from kittens was five times that of M θ from adult cats, thus establishing a direct correlation between the age-related susceptibility of cats and M θ from cats to FeLV. M θ of viremic cats were found to be infected with FeLV *in vivo*; virus titers were slightly higher than those obtained after *in vitro* infection of M θ . M θ from cats that had experienced regressive FeLV infection were not significantly more resistant to FeLV infection *in vitro* than were M θ from naive adult specific-pathogen-free cats. HC, which has been shown to enhance the *in vivo* FeLV susceptibility of cats, also enhanced the permissiveness of M θ from cats to FeLV *in vitro* (600-fold for M θ from adult cats and 200-fold for M θ) from kittens. M θ permissiveness to FeLV was highly sensitive to HC and occurred in M θ infected *in vivo* or *in vitro*. In parallel with the effect of HC on the natural resistance of cats to FeLV, administration of silica before virus inoculation also markedly enhanced the FeLV susceptibility of adult cats. Silica was toxic for isolated M θ but not for lymphocytes *in vitro*, and silica produced monocytopenia and neutrophilia, delayed skin allograft rejection, and augmented feline oncovirus-associated cell membrane antigen antibody responses *in vivo*. These experiments indicate that M θ were linked to the natural resistance of cats to FeLV and that the temporary elimination of M θ functions (e.g., by silica) and/or the conversion of the M θ -FeLV relationship from a nonpermissive to a permissive state (e.g., by corticosteroids) resulted in failure of early virus containment, in persistent virus amplification in hemolymphatic tissues, and in subsequent FeLV-related proliferative or antiproliferative disease.—*JNCI* 1981; 67: 889-898.

FeLV is transmitted by contact of susceptible cats with virus excreted in salivary and respiratory secretions of persistently infected cats (1-4). Whether lymphosarcoma, leukemia, or antiproliferative disease such as aplastic anemia occurs after virus exposure is determined by the cat's ability to contain FeLV replication in target hemolymphatic tissues in the first few weeks after FeLV exposure (5, 6). The capacity for early lymphoreticular restriction of FeLV is deficient in immature cats (5, 7) and can be abrogated in adult cats by treatment with adrenal corticosteroid (8) or by exposure to the immunosuppressive chemical carcinogen methylnitrosourea (9). It is plausible that the interaction of M θ with FeLV and with lc determines whether progressive infection and leukemogenesis or regressive infection and elimination of FeLV-infected cells occur (5, 6). On the basis of this premise and

observations in mice that demonstrate the obligatory role of mononuclear phagocytes in age-related resistance to viral infections (10-12) and to grafts of normal or neoplastic hemolymphatic cells (13-15), we have investigated the involvement of feline M θ in the pathogenesis of FeLV infection.

MATERIALS AND METHODS

Cats.—All cats used were from a hysterectomy-derived (16) SPF breeding colony devoid of horizontally transmitted feline viruses.

M θ collection and culture.—Peritoneal M θ were collected from SPF cats by intraperitoneal lavage with 50-300 ml of saline 4 days after ip injection of 50-200 ml of 6% thioglycollate (Difco Laboratories, Detroit, Mich.). M θ were washed in PBS and resuspended in growth medium consisting of McCoy's 5-A medium containing 40% horse serum, 0.18% NaHCO₃, 2% glutamine, 2% essential amino acids, 1% nonessential amino acids, 1% sodium pyruvate, 0.1% gentamicin, and 0.05% Mycostatin. M θ were counted with a hemacytometer and stained with 0.05% new methylene blue.

M θ function assays.—Assays of phagocytic function were performed in glass slide-mounted, 8-well chambers (Lab-Tek Products, Naperville, Ill.) 24 hours after M θ were seeded; each chamber contained 5 \times 10⁵ M θ (0.5 ml of 10⁶ M θ /ml).

EA phagocytosis and rosetting.—SRBC were sensitized with rabbit IgG antibody at a subagglutinating

⁶ Department of Microbiology, The Ohio State University.

dilution of 1:10,000. A 0.2% suspension of sensitized, washed SRBC (10^7 cells/ml) in M θ growth medium was incubated at 100 SRBC:1 M θ in the culture chambers. For EA rosette determination, cultures were incubated at 37°C for 30 minutes, and nonadherent SRBC were removed by repeated washings with PBS before methanol fixation and Giemsa staining. For EA phagocytosis, cultures were incubated for 2 hours at 37°C, and nonphagocytized SRBC were lysed in 0.83% ammonium chloride in 0.01 M Tris buffer before the slides were fixed and stained. For each assay, 200 cells were examined microscopically, and the percent M θ forming EA rosettes (at least 3 SRBC/M θ), the number of M θ phagocytizing EA, and the number of phagocytized EA per M θ were determined.

Assays for phagocytosis of unopsonized heat-killed *Candida pseudotropicalis* were patterned after the assay technique of Cohen and Cline (17). Twenty-four-hour-old cultures of *C. pseudotropicalis* were grown in Sabouraud's medium and killed by being boiled for 15 minutes. Suspensions of 100 heat-killed *C. pseudotropicalis*/M θ were incubated in M θ growth medium for 2 hours at 37°C. Cultures were then washed with PBS, fixed, stained, and counted as described above for EA phagocytosis.

Phagocytosis of 0.794- μ m-diameter polystyrene latex beads (Sigma Chemical Co., St. Louis, Mo.) was determined in a similar manner. A 1:100 dilution of the commercial stock latex bead suspension containing 30% latex solids was used.

Virus.—R-FeLV (18) was used for all experiments. A virus stock consisting of a 20% homogenate of thymic lymphosarcoma tissue produced by passage of R-FeLV in SPF cats was used for in vivo inoculations. The inoculum contained 10^5 FFU infectious FeLV/ml as determined for the clone 81 assay system (19). This R-FeLV stock was toxic to cell cultures when diluted to less than 1:50; therefore, an R-FeLV pool of higher titer (10^6 FFU/ml) and lower cytotoxicity was prepared by inoculation of CrFK (20) as described in the accompanying report (21). For all in vitro M θ inoculation experiments, the R-FeLV stock was prepared in CrFK.

FeLV infectivity assay.—The sarcoma-positive, leukemia-negative clone 81 of CrFK, originated by Fischinger et al. (19), was used for the assay of infectious FeLV, as described by Schaller and Olsen (22). The assays were performed in 16-mm-diameter, MultiWell culture dishes, as detailed in the accompanying report (21). We determined cell-associated or cell-free VI in FFU for each inoculated M θ culture by assaying separately media and freeze-thaw lysates of M θ collected by scraping adherent cells from the wells with a rubber policeman. The clone 81 indicator cells were inoculated with 1.0 ml of M θ medium or with 10^6 M θ . Cell-associated or cell-free VI was expressed per 10^5 M θ recovered from the cultures at the time of harvest.

FeLV inoculation of M θ .—All experiments involving FeLV infection of M θ were done in 25-cm² flasks (Falcon Plastics, Oxnard, Calif.) in which 3.2×10^6 M θ were seeded in 4 ml of M θ medium. Polybrene (4

μ g/ml) was incorporated into M θ growth medium when the cells were seeded. Then 25-cm² flask cultures, 24 or 48 hours old, of feline peritoneal M θ (3.2×10^6 M θ seeded) were inoculated with 1 ml of R-FeLV containing 10^6 FFU/ml (multiplicity of infection = 0.33). Cultures were incubated for 1 hour at 37°C, and M θ growth medium with Polybrene was added. Culture medium was changed after 2 days, and cultures were harvested for the VI assay at 4 days. In some experiments, parallel FeLV-inoculated M θ -containing flasks also were harvested at 7 days.

Inoculation and monitoring of cats for FeLV infection.—All cats were inoculated ip with 10^5 FFU of tissue origin R-FeLV. Blood samples were collected every 2 weeks for determination of FeLV GSA in blood cells (23) and of antibody titers to FOCMA (24).

Immunofluorescence assays for FeLV GSA and FOCMA antibody.—The procedure described by Hardy et al. (23), with minor modifications (25), was used for demonstration of FeLV GSA in blood leukocytes. The indirect membrane immunofluorescent procedure of Essex et al. (24) was used for determination of FOCMA antibody.

HC treatment of M θ .—HC sodium succinate (Abbott Laboratories, North Chicago, Ill.), 10^{-4} , 10^{-6} , and 10^{-8} M, was added to the M θ medium when the cultures were initiated.

[³H]dThd labeling of M θ .—Cultures of peritoneal M θ with and without HC were initiated in microtiter wells at a cell density of 10^5 M θ /well. At the time of seeding, M θ were labeled with 0.5 μ Ci of [³H]dThd (6.7 μ Ci/mmol; New England Nuclear Corp., Boston, Mass.) per 10^5 M θ , and cell-associated ³H incorporation was determined after 24, 48, and 72 hours by harvesting with a semiautomatic multiple sample processor and counting net dpm in a liquid scintillation spectrophotometer.

Silica.—Microcrystalline silicon dioxide with a mean particle diameter of 1.1 μ m was used (Minusil; Pennsylvania Glass Sand Corp., Pittsburgh, Pa.). Before use, the silica was washed in PBS, autoclaved, ultrasonicated, and incubated at 4°C for 24 hours in McCoy's 5-A medium containing 5% fetal bovine serum. The silica particles were thus coated with protein, as described by Allison et al. (26), and their specificity for M θ was enhanced by decreasing nonspecific cytotoxicity due to direct damage to cell membranes. The silica suspension was ultrasonicated again before 10 or 20 ml of a 200 mg/ml suspension was injected ip per adult cat. In vitro toxicity was determined by the exposure of M θ cultured in 8-well, glass slide chambers to various concentrations of silica added to the M θ medium 24 hours after the cultures were established. We evaluated subsequent morphologic changes by staining and microscopically examining M θ at 24, 48, and 72 hours after silica exposure.

RESULTS

Phagocytic function of peritoneal M θ from weanling kittens and adult cats.—Weanling (8-wk-old) SPF

kittens are highly susceptible to experimental FeLV infection, whereas adult SPF cats (≤ 4 mo of age) have substantial resistance to the same virus dose (7). To determine whether the greater susceptibility of immature cats to FeLV might correlate with an age-related deficit in M θ function, we evaluated the phagocytic capacity of thioglycollate-elicited peritoneal M θ collected from kittens and adult cats.

The phagocytic indices of M θ from weanling kittens and adult cats were not significantly different ($P < 0.10$, paired *t*-statistic) (table 1). Thus no evidence was obtained of an age-related general deficit in M θ function.

Susceptibility of M θ from kittens versus adult cats to FeLV.—To determine whether age-related differences in the susceptibility of cats to FeLV might correlate with specific differences in M θ susceptibility to FeLV (if not to general differences in M θ function), we inoculated thioglycollate-induced peritoneal M θ from 19 weanling and 18 adult SPF cats with R-FeLV *in vitro*. The mean permissiveness of M θ from kittens to productive FeLV infection was five times greater than that of M θ from adult cats ($P < 0.01$, paired *t*-statistic) (table 2). The maximum incidence of FeLV infection in M θ from kittens was approximately 1% (0.01 FFU/M θ inoculated); that of M θ from adult cats was 0.2% (table 2).

Effect of HC on the susceptibility of feline M θ to FeLV.—On the basis of the correlation between the age-related susceptibility of cats and M θ from cats to FeLV and of the previous observation (8) that treatment of adult cats with adrenal corticosteroid markedly enhanced their susceptibility to FeLV by impairing early containment of viral replication in lymphoreticular tissues, we examined the tenet that the glucocorticoid augmentation of the FeLV susceptibility of cats may correlate with glucocorticoid enhancement of M θ permissiveness to FeLV. Therefore, peritoneal M θ from kittens and adult cats were exposed to various concentrations of HC sodium succinate before they were inoculated with R-FeLV.

HC markedly enhanced the susceptibility of feline M θ to FeLV infection (text-fig. 1); the permissiveness of M θ from adult cats was increased over 600-fold and that of M θ from kittens, nearly 200-fold (table 3). The mean increase in total (cell-associated plus cell-free) infectious virus in HC-treated M θ from all cats tested was 300-fold (table 4). An average of 1.6 FFU of

^a Infectivity was determined for the clone 81 assay. Cells were harvested 4 days after inoculation.

FeLV/M θ was produced by HC-treated M θ cultures as compared with 0.005 FFU of FeLV/M θ in non-HC-treated M θ . M θ permissiveness to FeLV was quite HC-sensitive; 10⁻⁸ M HC, the lowest concentration tested, still enhanced FeLV production eightyfold (text-fig. 1). HC treatment increased M θ DNA synthesis twofold, as measured by [³H]dThd uptake, whereas FeLV replication increased 270-fold (text-fig. 2). HC treatment, therefore, markedly enhanced FeLV replication in M θ , rendered M θ from adult cats and kittens equally permissive, and elicited virus titers equal to those obtained with feline cells considered highly permissive for FeLV replication (e.g., CrFK or feline embryo fibroblasts).

FeLV replication in peritoneal M θ from viremic versus FeLV-exposed, nonviremic cats.—The objectives of these experiments were threefold: 1) to compare the magnitude of FeLV infection in peritoneal M θ of persistently viremic cats (in which FeLV replicates extensively in bone marrow myelomonocytic progenitor

cells) with that obtained after in vitro FeLV inoculation of Mθ of normal cats, 2) to determine whether Mθ from cats that had experienced self-limiting FeLV infection in vivo would be resistant to FeLV infection in vitro, and 3) to assess whether the FeLV permissiveness of Mθ from either group of cats could be augmented by HC treatment in vitro. Accordingly, thioglycollate-induced peritoneal Mθ were collected from persistently viremic, preleukemic cats and cultured as in previous experiments but without in vitro FeLV inoculation and in the presence or absence of HC. Peritoneal Mθ were collected also from adult cats that had been inoculated with R-FeLV 6-10 weeks previously and that had remained nonviremic and developed FOCMA titers of 1:16 by 4 weeks post inoculation. These Mθ were inoculated with FeLV in vitro with and without HC as in previous experiments.

Mθ from viremic cats were found to be infected in vivo and produced infectivity titers similar to ($P > 0.10$) those produced by Mθ from kittens infected with R-FeLV in vitro (table 5). The susceptibility of Mθ from FeLV-exposed nonviremic adult cats to FeLV infection in vitro was similar to that observed previously for Mθ from naive adult cats (table 5). In both instances, FeLV infection was enhanced by HC treatment in vitro (table 5). Thus we concluded that the level of productive FeLV in peritoneal Mθ derived from viremic cats approximated that obtained after in vitro infection and that previous self-limiting FeLV infection did not render Mθ resistant to reinfection.

Effect of systemic Mθ impairment on resistance of cats to FeLV.—Because the above in vitro experiments and previous in vivo experiments suggested that the age-related resistance of cats to FeLV correlated with early viral replication versus containment of FeLV by

Mθ, we investigated whether temporary elimination of Mθ in vivo would impair FeLV resistance. Microcrystalline silica was administered to adult cats as a single 2- or 4-g dose, (prorated by weight from studies in mice (27-33), 4 days before virus inoculation.

Silica pretreatment abrogated the natural resistance of cats to FeLV. Persistent viremia developed in 92% of cats treated with 4 g of silica as compared with 9% of non-silica-treated controls (table 6). The enhancement of FeLV susceptibility by silica was dose related: A 50% reduction in the silica dose produced an 80% reduction in the incidence of progressive FeLV infection (table 6).

In contrast to the minimal FOCMA antibody responses of viremic cats infected with R-FeLV in previous studies (7), 54% (5/11) of silica-pretreated viremic cats developed FOCMA antibody titers of $\geq 1:16$ (mean peak titer = 1:59) (table 7). Antibody titers occurred at a mean interval of 2.9 weeks after inoculation; titers peaked at a mean interval of 6.5 weeks and declined thereafter.

Silica treatment of cats produced monocytopenia, transient lymphopenia, and neutrophilia that were independent of R-FeLV inoculation. In silica-treated FeLV-exposed viremic cats, lymphopenia persisted and neutropenia developed by 4 weeks when all of the cats had become viremic (text-fig. 3). [Lymphopenia and neutropenia were previously observed consequences of FeLV infection of bone marrow cells and of the onset of viremia (5)].

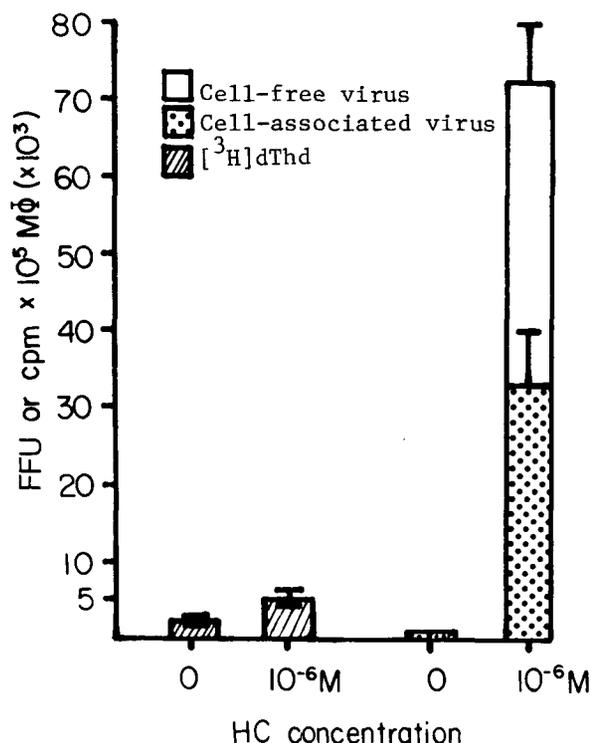

Two indices of cell-mediated immunity in silica-treated cats were moderately suppressed, independent of R-FeLV inoculation. The survival of cutaneous allografts was prolonged in 6 silica-treated cats compared with control cats grafted with skin from the same unrelated donor cat (table 8), and the blastogenic

response of blood lc to Con A was suppressed only transiently in silica-treated cats, despite the presence of lymphopenia (text-fig. 4).

Exposure of isolated feline MΦ to silica in vitro produced dose-related degeneration and death of MΦ but not of lc (tables 9, 10). Neither was the blastogenic response of feline lc impaired by incubation with concentrations of silica highly toxic to MΦ (table 10).

We concluded from these experiments that silica was an effective MΦ toxin in cats and that the silica enhancement of FeLV susceptibility in cats implicated MΦ in the resistance of cats to FeLV.

DISCUSSION

Investigations of experimental poxvirus, herpesvirus, and coronavirus infections in mice have established

that MΦ are central to the mechanism of age-related resistance to viral infection and that the resistance of MΦ to productive viral infection correlates with subsequent progression versus containment of viral infection (10-12, 22). Although the role of MΦ in host resistance to leukemogenic retrovirus infection has received less attention, it has been shown that impairment of MΦ function increases the susceptibility of mice to F- and R-MuLV (36-38), that splenic MΦ are among the earliest cells infected in mice susceptible to Friend virus disease (39), and that MΦ are involved in

the regression of Friend virus disease in resistant mice (40-43). In vitro, Mθ are relatively resistant to infection by F-MuLV (43) and, similarly, avian Mθ resist infection by the A and D-G subgroups of avian leukosis virus (44). We report that, although isolated feline Mθ also are relatively inhospitable hosts for FeLV, the age-related susceptibility of cats to FeLV (7) correlates with greater permissiveness of Mθ from kittens versus those from adult cats to FeLV infection in vitro. Moreover, agents that impair Mθ function in vitro and in vivo, i.e., HC and silica, also impair the FeLV resistance of adult cats. These findings support the tenet that the

autogenous resistance of cats to their leukemogenic retrovirus is M θ -dependent.

Cells that appear most important in the early phases of retrovirus infections *in vivo* are neither those most sensitive to viral infection nor those most readily propagated and studied *in vitro*. The MuLV replicate extensively in lymphoid cells *in vivo*; however, cultures of murine lc are relatively resistant to infection *in vitro* and require mitogenic stimulation to initiate infection of minority populations of cells (45, 46). Feline M θ , although relatively refractory to *in vitro* FeLV infection as compared with sensitive (but more artificial) host cells such as fibroblasts, still are more permissive than are feline lc (21). In the Friend virus system, Marcelletti and Furmanski (43) found that resident and thioglycollate-induced adult mouse peritoneal M θ were highly resistant to viral infection either *in vitro* or after transfer to the peritoneal cavity of viremic progressor mice. The proportion of M θ capable of entering DNA synthesis in a population greatly influenced permissiveness to F-MuLV infection (41). Addition of M θ colony-stimulating factor was required for the induction of productive infection in 0.03-0.1% of mouse peritoneal M θ (41). In our present studies with thioglycollate-elicited feline M θ , no specific growth-stimulating factors were added, yet cell-associated FeLV infectivity was induced in up to 0.1-0.3% of the inoculated M θ . In our earlier experiments (47), less favorable culture conditions produced lower indices of M θ infection; however, a greater divergence was observed between virus susceptibility of M θ from kittens versus those from adult cats, which suggests that suboptimal culture conditions are more sensitive in discriminating age-related differences in M θ viral susceptibility.

The magnitude of FeLV infection in peritoneal M θ from viremic cats was only slightly higher than that found after *in vitro* inoculation of M θ from kittens. This finding was unexpected in view of the extensive FeLV replication that occurs in myeloid progenitor cells of viremic cats (3, 5). Similar observations, however, were reported for M θ from F-MuLV viremic mice and suggest that most mature peritoneal M θ either are derived from uninfected myeloid clones or become refractory to or abort FeLV infection during the process of differentiation *in vivo* (44). Although our experiments with silica indicate that, as with F-MuLV, M θ are essential to the regression of FeLV infection in cats, peritoneal M θ of regressor cats are not rendered significantly more resistant to FeLV infection than are M θ of naive adult cats.

HC enhancement of M θ FeLV permissiveness was the most striking finding in this study. This phenomenon has not been described previously in retrovirus infections. HC enhanced M θ FeLV susceptibility a hundredfold to a thousandfold and resulted in virus titers in M θ from both kittens and adult cats comparable to those observed in sensitive embryonic cell cultures used to propagate FeLV *in vitro* (i.e., 1-2 FFU/M θ). Moreover, the presence of high-affinity binding sites for glucocorticoids on thioglycollate-elicited

peritoneal M θ in mice (48) is consistent with the premise that corticosteroids modulate the FeLV susceptibility of cats principally through corticosteroid action on M θ . DNA synthesis in feline M θ was doubled by HC treatment, whereas viral replication increased 250-fold. This finding implies that enhanced FeLV production was related not merely to increased numbers of cells entering the mitotic cycle, but probably also to an increase in number of M θ infected or an increased production of viral progeny by infected M θ . Because feline M θ were quite sensitive to HC (concentrations as low as 10^{-8} M being effective), cortisol levels obtainable under physiologic conditions could conceivably alter M θ FeLV susceptibility sufficiently to be responsible for the empirically observed effect (Hoover EA: Unpublished observations) of stress on the FeLV resistance of cats. Studies in mice have shown that both physiologic stress and administration of cortisone produce comparable impairment of M θ tumoricidal capacity (49).

Data concerning corticosteroids and retroviruses in other *in vitro* cell systems indicate that glucocorticoids exert their most dramatic effects in naturally nonpermissive cell populations and that both induction of viral receptors and induction of viral synthesis in cells nonproductively infected with retrovirus are plausible mechanisms. The epigenetic resistance of chicken M θ to avian leukosis viruses appears to reflect lack of the cellular receptor function responsible for facilitating viral penetration because the adsorption of restricted (A, D, G) and unrestricted (B, C) subgroup viruses to M θ is equivalent (44). Whether the virus envelope-cell receptor interactions responsible for restriction of avian leukosis virus by M θ could be abolished by glucocorticoid treatment of M θ would be of interest. Corticosteroids appear to produce relatively little effect on the replication of ecotropic MuLV in permissive mouse cells (50-52) but to enhance substantially the replication of 1) ecotropic MuLV in nonproductively infected mouse embryo cells (51-54), 2) ecotropic FeLV in nonproductively infected human embryo cells (55), and 3) xenotropic MuLV (53, 54) and FeLV (19) in heterologous cells. Cell transformation by defective murine and feline sarcoma viruses also is enhanced by corticosteroids, possibly through augmented helper leukemia virus replication in target cells (19, 55, 57). Thus available information concerning glucocorticoids and retrovirus expression supports the tenet that HC enhances the FeLV susceptibility of cats by converting the M θ -FeLV relationship from a nonpermissive state that leads to early virus containment and initiation of immune response to a permissive state that results in early viral amplification, virus-mediated immunosuppression, persistent viral infection, and leukemogenesis.

Although glucocorticoid receptors on M θ appear abundant (46), information concerning the effect of glucocorticoids on isolated M θ is relatively limited. In contrast to the effects of HC on feline M θ , corticosteroid treatment of mouse peritoneal M θ has been reported to inhibit M θ proliferation and protein synthesis (58) and to have variable effects on bacterial

phagocytosis and killing (59, 60). The proliferative capacity for long-term survival, lipogenesis, and sustenance of hematopoiesis by murine bone marrow M θ , however, is increased by HC (61, 62). Likewise, we have found that proliferation, survival, lipogenesis, and FeLV susceptibility of feline bone marrow M θ are augmented by HC (Hoover EA, Rojko JL: Unpublished data).

The abrogation of FeLV resistance by silica implicates M θ in the initial lymphoreticular containment of FeLV in cats. Likewise, M θ have been implicated in the control of MuLV leukemogenesis. Pretreatment of mice with silica or carrageenan enhances susceptibility to F-MuLV and R-MuLV infection, respectively (36, 37). Both spontaneous and statolon-induced regression of Friend erythroleukemia is dependent on M θ function and inhibited by systemic M θ toxins (37, 39, 63). Therefore, M θ can plausibly act in cats both as effector cells against FeLV-replicating cells and as initiators of the immune response through antigen presentation and other lc cooperation mechanisms (Rojko JL, Hoover EA, Finn BL, Olsen RE: Unpublished data).

The incidence (55%) and magnitude (mean titer = 1:59) of FOCMA antibody titers that accompanied the induction of persistent viremia in silica-treated, FeLV-exposed, viremic cats were more than tenfold greater than those observed in viremic cats in previous experiments by us and others (1-3, 7, 24, 64, 65). This finding suggests that short-term M θ removal by silica facilitated the induction of persistent viremia and that the subsequent adjuvant effect of silica (66) may have amplified the capacity for FOCMA antibody production, which has been shown to be present at least transiently in many viremic cats. In rodents, silica administration has been shown to enhance antibody response concomitant with regenerative hyperplasia of the mononuclear phagocytes after silica-induced depletion (66-68). A similar, though less dramatic, pattern in FOCMA antibody responses occurred in 29% of viremic adult cats given low doses of methylprednisolone before FeLV inoculation (8). The feasibility exists, therefore, that either reduction of the silica dose below that used in our present studies or prolongation of the interval between silica and FeLV administration would augment rather than impair FeLV resistance. In this regard, experiments examining the effect of the administration of M θ -stimulating substances, such as glucan or pyran copolymer, to kittens before R-FeLV challenge are in progress.

In agreement with studies on murine M θ (29, 69, 70), silica particles were rapidly toxic to isolated feline M θ , but neither cytotoxic effects nor impairment of blastogenic responses occurred in cultures of isolated feline lc exposed to concentrations of silica highly toxic to M θ (Rojko JL, Hoover EA, Finn BL, Olsen RG: Unpublished data). Also, in agreement with observations in mice (27), administration of silica to cats resulted in moderate prolongation of skin graft survival.

In effecting systemic M θ depletion in mice, silica also has been shown to deplete the ⁸⁹Sr-sensitive mononuclear cell population associated with genera-

tion of natural killer cells (71) and with the age-related, thymus-independent resistance of mice to grafts of normal or malignant hematopoietic cells (13, 14). Likewise, the mechanism of genetically determined resistance of mice to F-MuLV has been related to the ⁸⁹Sr-sensitive marrow cell population (72) and to the silica-sensitive systemic M θ population (41, 42). If one considers these observations in mice and that elimination versus amplification of FeLV-infected cells in cats occurs in the bone marrow and lymphoid tissues soon after virus inoculation (5), the role of both marrow silica-sensitive cells and natural killer cells in the mechanism of FeLV resistance in cats should be investigated.
