

Since January 2020 Elsevier has created a COVID-19 resource centre with free information in English and Mandarin on the novel coronavirus COVID-19. The COVID-19 resource centre is hosted on Elsevier Connect, the company's public news and information website.

Elsevier hereby grants permission to make all its COVID-19-related research that is available on the COVID-19 resource centre - including this research content - immediately available in PubMed Central and other publicly funded repositories, such as the WHO COVID database with rights for unrestricted research re-use and analyses in any form or by any means with acknowledgement of the original source. These permissions are granted for free by Elsevier for as long as the COVID-19 resource centre remains active.

ABSTRACT / INTRODUCTION

As the global pandemic of coronavirus disease-19 (COVID-19) progresses, many physicians in a wide variety of specialties continue to play pivotal roles in diagnosis and management. In radiology, much of the literature to date has focused on chest CT manifestations of COVID-19 (Zhou et al. [1]; Chung et al. [2]). However, due to infection control issues related to patient transport to CT suites, the inefficiencies introduced in CT room decontamination, and lack of CT availability in parts of the world, portable chest radiography (CXR) will likely be the most commonly utilized modality for identification and follow up of lung abnormalities. In fact, the American College of Radiology (ACR) notes that CT decontamination required after scanning COVID-19 patients may disrupt radiological service availability and suggests that portable chest radiography may be considered to minimize the risk of cross-infection (American College of Radiology [3]). Furthermore, in cases of high clinical suspicion for COVID-19, a positive CXR may obviate the need for CT. Additionally, CXR utilization for early disease detection may also play a vital role in areas around the world with limited access to reliable real-time reverse transcription polymerase chain reaction (RT-PCR) COVID testing.

The purpose of this pictorial review article is to describe the most common manifestations and patterns of lung abnormality on CXR in COVID-19 in order to equip the medical community in its efforts to combat this pandemic.

1. Ground glass densities

CXR is a less sensitive modality in the detection of COVID-19 lung disease compared to CT, with a reported baseline CXR sensitivity of 69% [4]. The most common reported CXR and CT findings of COVID-19 include lung consolidation and ground glass opacities².

Ground glass densities observed on CT may often have a correlate that is extremely difficult to detect on CXR (Figs. 1, 2).

Often, reticular opacities accompanying regions of ground glass attenuation are more easily appreciable on standard CXR (Fig. 3).

The hazy pulmonary opacities on CXR can sometimes be diffuse making identification challenging in some instances (Fig. 4).

2. Bilateral lower lobe consolidations

As opposed to community acquired bacterial pneumonia which tends to be unilateral and involving a single lobe [5], COVID-19 and other viral pneumonias typically produce lung opacities in more than

one lobe. Identifying multifocal air-space disease on CXR can be a significant clue to COVID-19 pneumonia. Early COVID-19 investigators have noted that the air-space disease tends to have a lower lung distribution and is most frequently bilateral [4] (Fig. 5).

3. Peripheral air space opacities

One of the most unique and somewhat specific features of COVID-19 pneumonia is the high frequency of peripheral lung involvement, often mirroring other inflammatory processes such as organizing pneumonia. Chung et al. reported that 33% of COVID-19 chest CTs had peripheral lung distribution [2] and Ng et al. reported an even greater incidence of up to 86% on chest CT [6]. Such peripheral lung opacities also tend to be multifocal, either patchy or confluent, and can be readily identified on CXR (Fig. 6).

Fig. 1. Portable CXR (left) with vague hazy densities in the right upper lobe (white arrow) which correspond to ground glass opacities (black arrow) on coronal image from contrast enhanced CT (right) performed the same day.

4. Diffuse air space disease

Diffuse lung opacities in patients with COVID-19 have a similar CXR pattern (Fig. 7) as other widespread infectious or inflammatory processes including acute respiratory distress syndrome (ARDS).

When lung disease involves the majority of the pulmonary parenchyma, patients are typically hypoxic and require intubation with mechanical intubation (Fig. 8).

Lung opacities may rapidly evolve into a diffuse coalescent or consolidative pattern within 1–3 weeks of symptom onset [1,7], often peaking at around 6–12 days after initial clinical presentation (Figs. 9, 10).

5. Uncommon CXR findings

Pleural effusions have been reported as exceedingly rare on CXR and CT in COVID-19 infected patients, and when present are most often identified late in the disease course [8].

Lung cavitation and pneumothorax are also rare findings in COVID-19 patients [8] but can occur (Fig. 11).

Localized large nodules have yet to be reported in the literature to this date (Fig. 12).

Diffuse chest wall subcutaneous emphysema and pneumomediastinum after intubation in the setting of COVID-19 infection has been described in one case report [9], as of the time of this writing. This

Fig. 3. CXR (left) with reticular and hazy left lower lobe opacities (black arrow) in a patient with COVID-19. Similar findings are present on the coronal CT from the same day (right).

phenomenon has also been reported previously in the setting of H1N1 viral infection [10].

Since the influx of cases began at our institution, we have noticed this to occur in several patients (Fig. 13). Potential mechanisms include alveolar rupture leading to interstitial emphysema from the currently recommended high positive end-expiratory pressure (PEEP) settings on COVID-19 ventilated patients according to the Macklin effect [11]. The diffuse alveolar damage in severe cases may also contribute to alveolar rupture. The exact mechanism requires additional investigation.

6. Conclusions

Patterns of COVID-19 lung disease can be identified on conventional chest radiography as well as chest CT. Typical verbiage when reporting patients with, or suspected COVID-19 on CXR include terms such as irregular, patchy, hazy, reticular, and widespread ground glass opacities. Grading disease severity based on total lung involvement is also important to relay to the clinicians. As the pandemic progresses, the medical community will frequently rely on portable CXR due to its
