Purpose: This study aimed to investigate associations of physical activity time (PAT) and sitting time (ST) independently and jointly with insomnia, depressive and anxiety symptoms among Chinese adolescents in the context of COVID-19.

Methods: A cross-sectional study including 965 adolescents (mean age = 15.26, SD = 0.46) was conducted in May 2020. PAT, ST and the symptoms of insomnia, depression and anxiety were assessed with the International Physical Activity Questionnaire Short Form, the Youth Self-Rating Insomnia Scales, the 9-item Patient Health Questionnaire and the Generalized Anxiety Disorder scale via an online survey platform. Logistic regression was used to analyze the association between COVID-19-related fear, PAT, ST and combinations of PAT and ST with insomnia, depressive and anxiety symptoms.

Results: COVID-19-related fear was associated with higher odds of insomnia, depressive and anxiety symptoms. PAT was associated with lower odds of insomnia and depressive symptoms, while ST was associated with higher odds of these three symptoms. After combining PAT and ST, the group with both low PAT and high ST was set as the referent. For insomnia, groups with low ST reported significantly lower odds of symptoms. For depression, groups with high PAT and/or low ST reported lower odds of symptoms. Regarding anxiety, only the group with both high PAT and low ST reported lower odds of symptoms. Generally, group with both high PAT and low ST reported lower odds of the three symptoms than the referent.

Conclusion: COVID-19-related fear was a risk factor for developing insomnia, depressive and anxiety symptoms among Chinese adolescents. Fortunately, moving more and sitting less were good for sleep and mental health in Chinese adolescents during the pandemic. Educators should help adolescents to be more physically active in their daily life in the primary prevention of adolescent insomnia, depression and anxiety.

Keywords: exercise, physical activity, sedentary behavior, sleep, mental health

Introduction

Since the novel coronavirus disease (COVID-19) swept the world extensively, there have been over 51 million confirmed cases of COVID-19, including more than 1 million deaths globally as of November 13, 2020.¹ As a result, social distancing measures that were implemented to slow the transmission of the COVID-19, together with fear of being infected with the COVID-19, are both linked with mental health problems (MHP) across different age groups including vulnerable

adolescents.^{2,3} Such problems seem to have gotten worse since the COVID-19 period started, particularly when indirectly comparing to the pre-COVID-19 prevalence because of their unprecedentedly altered lifestyle.⁴ For example, results of a cross-sectional study during part of the COVID-19 epidemic period revealed a high prevalence of insomnia symptoms (21.9%), depressive symptoms (44.9%) and anxiety symptoms (38.3%) among Chinese middle school students⁵ relative to results in previous non-COVID-19 studies.^{6–8} Of note, insomnia does not only negatively affect daytime function, but also may cause MHP in adolescents.⁹ Additionally, adolescents with MHP tend to be more susceptible to debilitating psychiatric illness in later life.¹⁰ Given the high prevalence of insomnia, depressive and anxiety symptoms among adolescents during such a stressful life-threatening event (the COVID-19 pandemic), it is essential to assess the prevalence of insomnia, depressive and anxiety symptoms and understand the key modifiable risk/protective factors so that health professionals can timely design effective interventions for the populations at risk of developing these symptoms.

Accumulating evidence has shown that mental health among adolescents can be improved by modifiable lifestyle behaviors, such as physical activity (PA) and sedentary behavior (SB).^{11,12} It is found that physical inactivity was associated with poor mental health during the pandemic.¹³ In contrast, more PA may help decrease the prevalence of depressive and anxiety symptoms.^{14,15} Regular PA during adolescence is not only of great benefit for physical health,¹⁶ but also has the potential to maintain mental well-being,¹⁷ while excessive time spent in sitting has been shown to have harmful effects on adolescent mental health.¹⁸ Thus, promoting PA and limiting SB concurrently might be promising to prevent adolescent mental problems during the COVID-19 and even post-pandemic.¹⁹ Previous empirical studies have provided the evidence base, for example, in a representative survey of Brazilian adolescents ($n = 100,839$, mean age = 14.28 years) where researchers found that less time spent sitting and more time spent physically active was associated with less insomnia.²⁰ Such beneficial effects of increased PA and reduced SB were consistently observed in terms of depression and anxiety.^{21,22} While the benefits of PA and problems associated with excessive SB are well documented in the absence of a pandemic, remaining active during the pandemic may be particularly important.^{17,21} Indeed, many

researchers have taken the potential role of PA into consideration when it comes to the impact of COVID-19 on MHP.^{14,23–25} For example, a study on Chinese general population found that not exercising was a common risk factor for sleep disorder, depression and anxiety.²³ Nevertheless, a recent study published in May 2020 found that irregular PA was associated with both higher odds of depression and anxiety and showed some protective effect for adolescent mental health during this global public health emergency.²⁶

Despite that valuable information linking PA/SB and mental health before the pandemic, as well as some empirical research conducted during the COVID-19 measuring PA, research about the associations between concurrent PA and SB with mental health among Chinese adolescent during this special period is still limited. Additionally, COVID-19-related fear as a unique variable was observed to associate with increased risks of developing MHP.^{27,28} A recent study showed that fear of COVID-19 causes anxiety, insomnia, and even suicide, reflecting the extreme psychological impacts related to COVID-19.²⁹ Although significant associations between fear and the negative mental outcomes have been well documented among adults,⁴⁸ literatures in terms of COVID-19-related fear among adolescents are limited. Thus, such fear perception should be considered as an important factor of symptoms concerned in this study, also an indispensable covariate when examining the relationships between PA/SB and MHP in the context of COVID-19. Moreover, researchers have begun to realize that various lifestyle behaviors are codependent and should be investigated simultaneously.³⁰ However, most previous studies have separately investigated the relationship(s) of PA or SB with health benefits, especially physical outcome measures.³¹ To fill this void, we therefore aimed to further explore the independent and joint role of PA and/or SB in insomnia, depressive and anxiety symptoms among Chinese adolescents in the context of COVID-19. Collectively, we conducted the present study with three specific aims: (1) to determine the prevalence of insomnia, depressive and anxiety symptoms in a Chinese adolescent sample during the COVID-19; (2) to explore associations between COVID-19-related fear with insomnia, depressive and anxiety symptoms; (3) to investigate associations between PA/SB with insomnia, depressive and anxiety symptoms.

Methods

Participant Recruitment

A cross-sectional study on junior middle school students was conducted between May 13 and 20 in 2020, shortly after reopening schools in Yizhou district, Hechi city, Guangxi province, Southern China. Guangxi province is an economically underdeveloped province in southern China, while Hechi city is one of the poorest areas in Guangxi. The rural population accounts for about 77% in Hechi.³² Many studies have found that adolescents living in underdeveloped rural areas are prone to MHP.^{33,34} Hence, it is very important to carry out the psychological survey of middle school students in rural areas (eg, Hechi city) during the COVID-19 pandemic. With a permission from the local educational department (Yizhou district; accounting for 15% of the population of Hechi city), the survey was conducted on junior middle school students in this district during the pandemic.³⁵ There are 30 public middle schools with 38,407 students in Yizhou.³⁵ Among all the possible schools in Yizhou, ten schools were randomly selected for our sample recruitment.

Of note, to meet the age requirement of the PA questionnaire and ensure that participants were able to understand the questionnaire content (it is detailed in measurement), only students aged over 15 years in these schools were invited to attend this study, leading to an initial sample size of 1054 students. After removing participants with incomplete and missing data, information of 965 adolescents finally were valid. Based on previous studies on similar topic during the COVID-19 pandemic, the sample was calculated using G*Power 3.1 with the following assumptions: an expected prevalence (40.0%) of symptoms among Chinese adolescents, 1.5 odds ratio (OR) of symptoms among low PAT or high ST, margin of error of 5% and power of 80%.^{36–39} This gives a total sample size 778. The finally recruited sample ($n = 965$) goes beyond this, which is sufficient for formal analysis (eg, be sufficient to meet the statistical requirements).

Procedure

With the assistance of the local education authority, official approvals were obtained from the selected schools. In consideration of safety during the pandemic, all participants completed the questionnaires via an online survey platform in which instructions were described. The questionnaires contained scales of PAT, ST, insomnia symptoms, depressive symptoms, anxiety symptoms, and COVID-19-related fear,

as well as some socio-demographic information. Prior to data collection, head teachers of the participants have informed participants' guardians regarding the investigation. Subsequently, the informed consent forms were delivered to the participants and their parents. After obtaining their consent, the survey was started. The purpose of this study was explained to all participants and it was highlighted that all the collected data would be analyzed in an aggregated manner with personal information being kept in strict confidentiality. This study was conducted in accordance with the Declaration of Helsinki and approved by both the administration committees of the surveyed schools and the Human Research Ethics Committee of Shenzhen University (Code number: 2,020,005).

Measurements

Physical Activity and Sitting Time

Daily PA time and sitting time were self-reported using the International Physical Activity Questionnaire Short Form (IPAQ-SF), which was developed as a surveillance instrument to measure multiple domains of PA.^{40,41} Of note, it has widely been recommended to measure PA of individuals aged between 15 and 65 years.⁴⁰ The IPAQ-SF asks respondents to report the frequency and duration in each PA (vigorous-intensity activities, moderate-intensity activities and walking), as well as the duration of daily sitting during the last 7 days. The Chinese version of the IPAQ-SF has been confirmed adequately reliable and valid in previous studies.⁴¹

Insomnia Symptoms

Insomnia symptoms were measured using the Chinese version of the Youth Self-Rating Insomnia Scales (YSIS).⁴² The YSIS consisted of 8 items with each item that is rated on a 5-point scale. A total YSIS score that ranged from 8 to 40 can be obtained, with a higher total score indicating a greater severity over the past month. Participants who scored 22 and above were identified as having insomnia symptoms, whereas participants with score of less than 22 had no insomnia symptoms. The psychometric properties of the YSIS were assessed in a large sample of Chinese adolescents with an internal consistency reliability coefficient of 0.80 and 2-week test-retest reliability coefficient of 0.82.⁴² In the current study, the Cronbach's α coefficient was 0.90.

Depressive Symptoms

The Chinese version of the 9-item Patient Health Questionnaire (PHQ-9) was used to measure level of

depressive symptoms.⁴³ Each item that can earn 0 to 3 points (0 = “not at all” to 3 = “nearly every day”), and a total score ranged from 0 to 27 (higher points indicating more severe depressive symptoms). Total scores of 5, 10, 15, and 20 were identified as the cut-off of mild, moderate, moderately severe and severe symptoms of depression, respectively. Thus, a total score of 5 was set as a cut-off point to categorize participants into two groups: no depressive symptoms (PHQ-9 score <5) and depressive symptoms (PHQ-9 score \geq 5). The Chinese version of PHQ-9 has been widely used and well validated in Chinese adolescents, possessing adequate internal consistency of 0.84,^{5,44} which is further supported by the current study, with a Cronbach’s α coefficient of 0.90.

Anxiety Symptoms

Anxiety symptoms were measured using the Chinese version of the Generalized Anxiety Disorder scale (GAD-7), which is an appropriate measure of anxiety symptoms in general.^{45,46} Each item has four response options (0 = “Not at all” to 3 = “Nearly every day”). Each participant can obtain a total score that ranged from 0 to 21, with higher score indicating more severe anxiety. Total scores of greater than or equal to 5, 10, 15, and 20 were identified as mild, moderate, moderately severe and severe anxiety, respectively. Thus, with the cut-off point set at 5, participants were categorized into two groups: no anxiety symptoms (GAD-7 score <5) and anxiety symptoms (GAD-7 score \geq 5). The psychometric properties of the GAD-7 have been validated in Chinese adolescents,^{5,33,45} which is further supported by the current study with a good internal consistency (Cronbach’s α coefficient = 0.93).

COVID-19-Related Fear

Fear was measured using the Chinese version of the Fear of COVID-19 Scale (FCV-19S).^{47,48} It consisted of 7 items, with each item that can be responded on a 5-point Likert scale (strongly disagree = 1 to strongly agree = 5). Its total score (summation of individual response items) ranged from 7 to 35, with higher scores indicating greater COVID-19-related fear. The psychometric properties of the FCV-19S have been confirmed in a Chinese population with a good internal consistency reliability (α = 0.92), composite reliability (CR = 0.92) and good structural validity.⁴⁷ Good internal consistency was also presented in this study with a Cronbach’s α coefficient of 0.94.

Socio-Demographic Information

Socio-demographic information was collected via a self-reported questionnaire, including age, gender (male/female). Their family economic status was also collected, indicated by household monthly income per person (Chinese currency [Yuan as unit] - RMB: <2000/2000–3000/ \geq 3000) in this study. Additionally, they reported their left-behind status (left-behind/non-left-behind; left-behind children are prevalent in modern China, referring to the children who are under 18 years old and left at rural residences for at least 6 months by either one or both of parents migrating to work in cities). Studies have indicated high risk of mental problems among Chinese left-behind children.^{34,49}

Statistical Analyses

Descriptive analyses were performed for participant characteristics. Descriptive data are presented as mean with standard deviation (SD) for continuous variables and frequency with percentage for categorical variables.

Here, according to the median values in this sample, participants were categorized based on the cut-off points of 1.5h/d for PAT and 4h/d for ST, respectively. Thus, the participants were divided into two categories for PAT (low PAT or high PAT). Similarly, the participants were classified into two categories for ST (low ST or high ST). Then, the participants were cross-tabulated into 4 (2 \times 2) groups (ie, Group I : low PAT + high ST; Group II : low PAT + low ST; Group III: high PAT + high ST; Group IV: high PAT + low ST).

Logistic regressions were used to examine the associations between COVID-19-related fear, PAT, ST and combination of PAT and ST with the symptoms of insomnia, depression and anxiety. Socio-demographic factors (ie, age, gender, left-behind status, and household monthly income per person) and COVID-19-related fear were included as confounding variables when examining the independent and joint associations between PAT and ST with these symptoms. To examine the independent associations between PA/SB with the symptoms of insomnia, depression and anxiety, we also mutually adjusted exposures (PAT and ST) for each other (ie, when PAT was modeled as the main exposure, the analysis was adjusted for ST, and when ST was modeled as the main exposure, the analysis was adjusted for PAT). Next, the joint associations between PAT and ST with the symptoms of insomnia, depression and anxiety were examined. Using Group I (low PAT + high ST) as the referent,

we compared the odds ratios (OR) of symptoms between Group I and other groups after adjusting for controlled variables. All analyses were performed using SPSS for Windows, version 26.0. The statistical significance was set at $p < 0.05$ (two-tailed) for interpretation of the results.

Results

The final sample in this study consisted of 965 adolescents aged 15–17 years (mean age: 15.26 ± 0.46), of which females accounted for 42.4%. Of all participants, 49.9% of participants were categorized to low PAT while 54.0% of participants were recognized as high ST. Meanwhile, 34.9%, 45.7% and 34.4% participants reported insomnia, depressive and anxiety symptoms in this study,

respectively. More detailed descriptive characteristics of the participants are shown in Table 1.

Table 2 presents the independent associations between COVID-19-related fear, PAT and ST with insomnia, depressive and anxiety symptoms. Higher COVID-19-related fear was significantly related with the occurrence of insomnia symptoms (OR = 1.03 [1.01–1.05], $p < 0.01$), depressive symptoms (OR = 1.03 [1.01–1.05], $p = 0.001$) and anxiety symptoms (OR = 1.06 [1.04–1.08], $p < 0.001$). Regarding the independent associations of PAT and ST with insomnia, depressive and anxiety symptoms, participants with high PAT reported less opportunities to develop insomnia symptoms (OR = 0.71 [0.54–0.95], $p < 0.05$) and depressive symptoms (OR = 0.71 [0.54–0.93], $p < 0.05$) than those with low PAT after adjusting for age, gender, left-behind status, household monthly income per person, COVID-19-related fear and ST. In contrast, participants with high ST were more likely to develop insomnia symptoms (OR = 1.79 [1.36–2.37], $p < 0.001$), depressive symptoms (OR = 1.65 [1.26–2.16], $p < 0.001$) and anxiety symptoms (OR = 1.47 [1.11–1.94], $p < 0.01$) than those with low ST after adjusting for age, gender, left-behind status, household monthly income per person, COVID-19-related fear and PAT.

Table 3 shows the joint associations of PA and SB with the symptoms of insomnia, depression and anxiety. For insomnia, Group II (OR = 0.56 [0.38–0.83], $p < 0.01$) and Group IV (OR = 0.40 [0.27–0.59], $p < 0.001$), namely the two groups with low SB, reported significantly lower odds than the reference group (ie, Group I). For depression, Group II (OR = 0.55 [0.38–0.80], $p < 0.01$), Group III (OR = 0.65 [0.45–0.93], $p < 0.05$) and Group IV (OR = 0.43 [0.30–0.63], $p < 0.001$), namely the groups with high PA and/or low SB, were all significantly associated with lower odds of symptoms than the reference group. For anxiety, only the group with high PAT and low ST concurrently (ie, Group IV) was associated with lower odds of symptoms than reference group (OR = 0.65 [0.43–0.97], $p < 0.05$). Generally, compared to the reference group with both unhealthy behaviors (ie, low PAT + high ST), participants with both healthy behaviors (ie, high PAT + low ST) demonstrated significantly lower prevalence of insomnia symptoms (OR = 0.40 [0.27–0.59], $p < 0.001$), depressive symptoms (OR = 0.43 [0.30–0.63], $p < 0.001$) and anxiety symptoms (OR = 0.65 [0.43–0.97], $p < 0.05$).

Table 1 Descriptive Characteristics of the Participants

Variables	n (%) or Mean \pm SD
Age	15.26 \pm 0.46
Gender	
Male	556 (57.6)
Female	409 (42.4)
Left-behind status	
Left-behind	305 (31.6)
Non-left-behind	660 (68.4)
Household monthly income per person (yuan)	
<2000	334 (34.6)
2000–3999	416 (43.1)
\geq 4000	215 (22.3)

Notes: Data are presented as OR (95% CI). * $p < 0.05$, ** $p < 0.01$, *** $p < 0.001$. Group I: low PAT + high ST; Group II: low PAT + low ST; Group III: high PAT + high ST; Group IV: high PAT + low ST. Using Group I as the referent, the odds ratios of the three symptoms between Group I and other groups were compared after adjusting for age, gender, household monthly income per person, left-behind status, COVID-19-related fear.

prevalence of insomnia, depressive and anxiety symptoms, independent and joint associations between PAT and ST with these symptoms, as well as the associations between COVID-19-related fear with these symptoms. The prevalence of insomnia, depressive and anxiety symptoms in this sample was 34.9%, 45.7% and 34.4%, respectively. More COVID-19-related fear was correlated with higher odds of insomnia, depressive and anxiety symptoms, while high PAT and low ST were associated with lower odds of insomnia and depressive symptoms. Compared to the reference group with unhealthy behaviors (low PAT and high ST), the group with both healthy lifestyle behaviors (high PAT and low ST) was significantly associated with lower odds of

insomnia, depressive and anxiety symptoms. Additionally, only the group with concurrent high PAT and low ST presented significantly lower odds than the reference group. Possible explanations for these results are presented in detail below.

Prevalence of insomnia, depressive and anxiety symptoms in this study was generally high, which reflects the psychological impact of the pandemic to some extent. One reason for such a high prevalence may be because all the participants were junior high school students over 15 years old; thus, a large proportion of our participants were students in Grade 3, who were facing the pressure of senior middle school entrance examination (the most important examination for junior middle school students). Besides,

our sampling process was conducted in Guangxi province, one of the economically backward areas in China, nearly a third of the students were left-behind children. Previous research has found that left-behind children were more likely to develop mental health problems as they experience separation from harmonious parent-child interactions.⁴⁹ A relatively low cut-off point of 5 of the PHQ-9 and GAD-7 may also explain the high prevalence. Nevertheless, our results were similar to a large-scale study with 11,835 Chinese adolescents conducted in March 2020 (two months earlier than this study), which assessed depressive and anxiety symptoms by the PHQ-9 and GAD-7 and adopted the same cut-off point as our study. This is a warning that negative impact of the pandemic on adolescent mental health, may be continuous and long term despite that COVID-19 situation has been better in China.

Results in the current study indicated that greater COVID-19-related fear was significantly associated with higher levels of insomnia, depressive and anxiety symptoms. This is consistent with a pre-COVID-19 study indicating that people who suffered from fear tended to develop insomnia symptoms.⁵⁰ Recent studies conducted during the COVID-19 also suggested that fear of COVID-19 was associated with psychological distress and life dissatisfaction.²⁸ Aggregated fear of COVID-19 may even lead to suicide.²⁹ Taken together, fear caused by life-threatening event like COVID-19- would increase the probability of developing mental health problems, indirectly reflecting the psychological impact of the COVID-19. The fear and psychological distress related to the pandemic has been found to be associated with the stressors such as frustration, inadequate information, and problematical media exposure.⁵¹ Thus, parents and educators should pay attention to adolescents' fear to COVID-19 and their consumption of pandemic-related media coverage, and help adolescents with proper knowledge on the COVID-19.

Since the pandemic has been such a great threat to the mental health of adolescents, it is very important to figure out the protective factors to prevent or intervene the potential MHP. Generally, it is considered that either high PA or low SB is healthy for adolescents.⁵²⁻⁵⁴ This study conducted during the COVID-19 also supported this idea. Specifically, participants with high PAT were less likely to develop insomnia and depressive symptoms than counterparts with low PAT, while high ST group was more likely to develop insomnia, depressive and anxiety than those with

low ST even after mutually adjusting for each other of PAT and ST. Although our data cannot render a causal inference about the association, previous research can provide some indications of a potentially causal relationship, which would underpin our assertions. In terms of PA, for example, a randomized controlled trial indicated that 30-minute morning running during weekdays for three consecutive weeks had positive impact on sleep quality and psychological functioning among healthy adolescents relative to a control group.⁵⁵ In addition, a prospective cohort study found that increasing ST (measured by anti-graph) was associated with greater level of depression at age 18 years relative to its baseline assessment of children aged 12-16 years.¹² Besides, it was reported that a one-week sedentary behavior-inducing intervention had deleterious effects on anxiety among an active youth population as compared with a control group.⁵⁶

Despite extensive research on the efficacy of PA/SB, the potential mechanism through which they produce mental health benefits among adolescents remains unclear. Nevertheless, biological, psychological and behavioral mechanisms have been suggested for the relationships between PA with mental health of young people.⁵⁷ Biological mechanism hypothesis suggests that PA improves mental health via structural and functional changes in the brain, such as improving levels of mood-regulating neurotransmitters in the brain or the production of cortisol.⁵⁸⁻⁶⁰ PA was also found to be a mediator in the relationship between inflammation and depression in adults, but relevant evidence from adolescents is limited.^{61,62} Psychological mechanism hypothesis suggests that PA makes it more accessible for social interaction and social support, improving the self-esteem, self-efficacy and perceived competence and improvements in body image.^{63,64} Behavioral mechanism hypothesis suggested that PA may improve self-regulation and coping skills which may help effectively stay positive mentally.⁵⁷ Regarding the positive impact on sleep, it is expected that by energy consumption, PA would increase the need for sleep at night to reduce metabolic requirements for energy conservation and body restoration.⁶⁵ Moreover, physically active individuals tend to maintain other healthy behaviors, such as favorable diet patterns which are associated with better sleep quality and mental health.^{66,67} Regarding the undesirable influence of SB, previous research has suggested that it is also associated with inflammation, which is a core feature of major depression.^{68,69} A meta-analysis suggested that high levels

of SB are associated with higher levels of anxiety symptoms, and the associations remain largely similar, regardless of age, health status and measurements.⁷⁰ There is some provisional evidence to suggest that standing or breaking up prolonged periods of sitting might help alleviate the harmful effect of SB on metabolism in adolescents,⁷¹ but more research to clarify the mechanism of SB on sleep and mental health are needed.

Taken together, owing to the independent impact of increased PA or limited SB, it is expected that increasing PA and limiting SB concurrently would be a better protective factor to improve sleep and mental health than only focusing on PA or SB among adolescents. This expectation is supported by the main findings of the joint roles of PA and SB in this study: combinations with healthy behaviors (high PAT + low ST) were all significantly associated with lower odds of insomnia, depression and anxiety symptoms than the combinations with unhealthy behaviors (low PAT + high SB). The presence of health-promoting behaviors may produce a cumulative effect on mental health outcomes.³¹ Most current research findings have suggested that meeting behavior recommendations (eg, adolescents aged 14–17 years need to engage in at least 60 min per day of moderate-to-vigorous PA) may aid in attaining better physical and mental health in adolescents.^{30,72} In fact, as mentioned before, many researchers have expressed their interest in modifiable lifestyle behaviors when the psychologists seek to figure out ways to combat the burden on mental health caused by the pandemic.^{26,73} Therefore, in the follow-up work, more research should look into the related factors with the time distribution on PA and SB among adolescents as the pandemic is still going on.

Another interesting finding in this study was found in the association between PA and anxiety symptoms: no significant difference on anxiety existed between high PAT and low PAT. This may implicate the weak association between PA and anxiety, which is consistent with a conclusion given in a review paper that PA only has a small beneficial effect for alleviating anxiety symptoms.⁷⁴ Moreover, after combining PA and SB, as compared to the reference group (ie, low PAT + high ST), only the group with high PAT and low ST concurrently was associated with lower odds of anxiety symptoms, while only the groups with low ST were associated with lower odds of insomnia symptoms. Our results suggest that a high level of PA may not alleviate the effect of excessive SB on mental health outcomes. Findings in the present study partially agrees with a previous study, which found that adolescents with concurrent high PA and high SB might be also experiencing poor mental health.⁷⁵ Besides, a cross-sectional study

demonstrated that screen time, closely related with sitting time, had greater impact on mental health than PA.⁷⁶ However, compared with the attention paid to PA, information on the relationships between SB and mental health is less available, which highlights the importance to investigate the underlying mechanism of SB on mental health in future research. More importantly, these findings reaffirm that when non-health-promoting behaviors coexist with health-promoting behaviors, the benefit of healthy behaviors may be eliminated.³¹ Thus, future interventions should consider how behaviors cluster and interact with each other. Rather than putting too much emphasis on one single lifestyle behavior, especially in the context of public health emergency, our findings reinforce the importance of promoting PA and limiting SB concurrently in preventing symptoms of insomnia, depression and anxiety in Chinese adolescents during the COVID-19 pandemic.

Some limitations in our study should be mentioned. First, the study involved only junior middle school students in Yizhou district, Hechi city. Even though we have included left-behind status and household income as confounding factors, one should be cautious in generalizing our findings to all Chinese adolescents. Future studies are encouraged to replicate or negate our research findings based on young population with a wider range of ages and socioeconomic status. Second, the nature of cross-sectional design allows no inferences on the causality of any associated factor. More comprehensive longitudinal studies are needed to better understand the complex and potentially reciprocal relationship between the variables (ie, PA, SB, insomnia, depressive and anxiety symptoms). Third, the self-reported information may cause bias due to the social desirability effect and memory error. Studies with larger sample size and objective measure are highly recommended in future studies.⁷⁷ Fourth, although the presence of mental problems was assessed by the standardized questionnaires, these measures are not completely equivalent to clinical diagnoses; thus, future studies with diagnostic interviews should be used.

Conclusion

The present study found that COVID-19-related fear is significantly associated with the prevalence of insomnia, depressive and anxiety symptoms. Besides, it provided further evidence that high PA and low SB contributed to better sleep and related mental outcomes, while the co-existence of these two behaviors could confer a greater benefit in adolescents. This study suggested that moving more and sitting less is good for sleep quality and mental health for Chinese adolescents

during COVID-19 pandemic. For the prevention and intervention of insomnia, depression and anxiety, it is worthwhile to pay attention to the joint roles of PA promotion and SB reduction in adolescents, by encouraging adolescents to be physically active and decrease sedentary behavior. Future studies with longitudinal design and objective measures are encouraged to provide more information on this topic.

Psychology Research and Behavior Management

Dovepress

Publish your work in this journal

Psychology Research and Behavior Management is an international, peer-reviewed, open access journal focusing on the science of psychology and its application in behavior management to develop improved outcomes in the clinical, educational, sports and business arenas. Specific topics covered in the journal include: Neuroscience, memory and decision making; Behavior modification and management; Clinical

applications; Business and sports performance management; Social and developmental studies; Animal studies. The manuscript management system is completely online and includes a very quick and fair peer-review system, which is all easy to use. Visit <http://www.dovepress.com/testimonials.php> to read real quotes from published authors.

Submit your manuscript here: <https://www.dovepress.com/psychology-research-and-behavior-management-journal>
