

# The origin of the lower fourth molar in canids, inferred by individual variation

Masakazu Asahara

College of Liberal Arts and Sciences, Mie University, Tsu, Mie, Japan

## ABSTRACT

**Background:** An increase in tooth number is an exception during mammalian evolution. The acquisition of the lower fourth molar in the bat-eared fox (*Otocyon megalotis*, Canidae, Carnivora, Mammalia) is one example; however, its developmental origin is not clear. In some canids (Canidae), individual variation exist as supernumerary molar  $M_4$ . This study focuses on the acquisition of the lower fourth molar in canids and proposes that the inhibitory cascade model can explain its origin.

**Methods:** Occlusal view projected area of lower molars was determined from 740 mandibles obtained from *Canis latrans*, *Nyctereutes procyonoides*, and *Urocyon cinereoargenteus* museum specimens. For each molar, relative sizes of molars ( $M_2/M_1$  and  $M_3/M_1$  scores) affected by inhibition/activation dynamics during development, were compared between individuals with and without supernumerary molar ( $M_4$ ).

**Results:** Possession of a supernumerary molar was associated with significantly larger  $M_2/M_1$  score in *Canis latrans*,  $M_3/M_1$  score in *Nyctereutes procyonoides*, and  $M_2/M_1$  and  $M_3/M_1$  scores in *Urocyon cinereoargenteus* compared to individuals of these species that lacked supernumerary molars.

**Discussion:** We propose that, in canids, the supernumerary fourth molar is attributable to reduced inhibition and greater activation during molar development. In the bat-eared fox, altered inhibition and activation dynamics of dental development during omnivorous-insectivorous adaptation may be a contributing factor in the origin of the lower fourth molar.

## INTRODUCTION

During the evolution of mammalian dentition, the number of teeth usually declines (*Davit-Béal, Tucker & Sire, 2009; Ungar, 2010; Jernvall & Thesleff, 2012*). While there are possible examples of secondary acquisition of recently lost teeth ( $M_3$  in callitrichine monkey: *Scott, 2015*), increased tooth number is a rare evolutionary event. Only whales (Cetacea), armadillos (Cingulata) and the bat-eared fox (*Otocyon megalotis*, Canidae, Carnivora) have evolved to increase the number of permanent teeth beyond the ancestral eutherian basic dental formula (I 3/3, C1/1, P 4/4 M 3/3) (*Ungar, 2010*). Some species, such as the manatee (*Trichechus*, Trichechidae, Sirenia), pigmy rock wallaby (*Petrogale concinna*, Macropodidae, Marsupialia), and silvery mole-rat (*Heliophobius argenteocinereus*, Bathyergidae, Rodentia), exhibit continuous horizontal replacement of

teeth (Ungar, 2010; Gomes Rodrigues et al., 2011). However, only the bat-eared fox (*O. megalotis*) has shown an increase in tooth number, accompanied by neither morphological simplification nor continuous horizontal replacement. The dental formula in the bat-eared fox is I 3/3, C1/1, P 4/4 M 3–4/4–5, with these animal usually possessing an upper  $M^3$  and lower  $M_4$  that ancestral Canidae lacked (Sillero-Zubiri, 2009; Ungar, 2010), and this is considered a rare case of increased functional teeth number beyond that of the extant eutherian basic dental formula (Sillero-Zubiri, 2009; Ungar, 2010).

Bat-eared foxes are primarily insectivorous (Sillero-Zubiri, 2009), with a molar morphology comprising an undeveloped carnassial blade, equally sized molars (in relation to the other canids) and increased number of molars, which are attributable to an adaptation to an insectivorous diet (Wang & Tedford, 2008; Asahara, 2013; Asahara et al., 2016). It has been proposed that this dentition is suitable to a diet of insects that are small relative to the body size of the bat-eared fox, with a larger molar row grinding surface that enables greater chewing efficiency (Asahara, 2013; Asahara et al., 2016). However, this does not explain the presence of the fourth molar, the developmental origin of which remains unclear.

Individual variations in tooth number (supernumerary and missing teeth) have been reported in many mammals (e.g. Miles & Grigson, 1990). In some cases, as discussed by Asahara, Kryukov & Motokawa (2012), individual variations may underpin evolution, that is, fixation of the variation could initiate a new dental formula. In the present study, the source of the  $M_4$  in the bat-eared fox was investigated based on examination of supernumerary teeth in related species.

There are several reports of supernumerary molars in Canidae, including  $M^3$  and  $M_4$  along the normally aligned tooth row in coyote (*Canis latrans*) (Hall, 1940; Paradise, 1966) and gray fox (*Urocyon cinereoargenteus*) (Hall, 1940). Wolsan (1984) categorized two types of supernumerary tooth generation: (1) creation of additional tooth germ and (2) splitting of a tooth germ. Type 1 can explain most of the supernumerary teeth that appear in positions where the ancestor possessed teeth, whereas type 2 can explain the eruption of supernumerary teeth that possess abnormal morphology relative to adjacent teeth. While the  $M^3$  in the coyote can be regarded as type 1 and “atavistic,”  $M_4$  is not readily explained in this manner. Although ancestral caniforms possessed  $M^3$  (Wang, 1994; Tomiya, 2011), the last ancestor possessing a functional  $M_4$  may be as early as the Mesozoic period, since the common ancestor of Placentalia possessed only three lower molars (O’Leary et al., 2013).

A previous experimental study established a developmental model termed the inhibitory cascade model (IC model) to explain relative molar size among three lower molars in mammals as resulting from the balance of inhibition and activation molecules during dental development (Kavanagh, Evans & Jernvall, 2007). In this model, activation molecules from the mesenchyme stimulate the formation of distal molars ( $M_2$  and  $M_3$ ), which makes them larger in relation to  $M_1$ , whereas inhibition molecules secreted from  $M_1$  suppress distal molars growth ( $M_2$  and  $M_3$ ) (Kavanagh, Evans & Jernvall, 2007). According to the balance of these two factors, the relative size of  $M_1$ ,  $M_2$ , and  $M_3$  (typically shown numerically as  $M_2/M_1$  and  $M_3/M_1$  size ratios; the size is defined as projected

tooth area from occlusal view) result in a pattern of  $M_1 > M_2 > M_3$ ,  $M_1 = M_2 = M_3$ , or  $M_1 < M_2 < M_3$  (Kavanagh, Evans & Jernvall, 2007). This model has previously been applied to explain dental variation in Carnivora (Polly, 2007; Halliday & Goswami, 2013; Asahara, 2013; Asahara et al., 2016).

The IC model can also explain the loss of  $M_3$  during murine evolution, such that greater inhibition and lower activation in experimental mice organs resulted in the disappearance of  $M_3$ , coinciding with changes in the  $M_2/M_1$  and  $M_3/M_1$  ratios. This corresponds to the dentition of the murine species *Hydromys chrysogaster*, which lacks the  $M_3$  (Kavanagh, Evans & Jernvall, 2007). Asahara (2013) reported the relationship between dental anomalies ( $M_3$  loss) and the IC model in canids, in which  $M_2/M_1$  scores of individuals that lost  $M_3$  were lower (indicating higher inhibition and lower activation) than the scores in normal individuals in local populations of raccoon dog (*Nyctereutes procyonoides*) and arctic fox (*Vulpes lagopus*) (Asahara, 2013). Evolutionary loss of  $M_3$  in murines and canids is thus considered attributable to inhibition/activation dynamics of dental development. Conversely, Kavanagh, Evans & Jernvall (2007) reported one case in which a supernumerary molar ( $M_4$ ) appeared in mice following suppression of inhibition molecules, indicative of an increase in molar number and altered inhibition/activation dynamics.

The working hypothesis for this study is that the fourth lower molars in the bat-eared fox and the supernumerary molar in some other canid species are generated by reduced inhibition and greater activation during dental development. This was tested by comparing the relative size of molars in locations of three canid species with some individuals possessing a supernumerary molar ( $M_4$ ).

## MATERIALS AND METHODS

Mandible specimens (dentary bones and molars) of 451 *Canis latrans* (from the United States National Museum of Natural History), 153 *Nyctereutes procyonoides* (from the Primate Research Institute, Kyoto University, Japan), and 136 *Urocyon cinereoargenteus* (from the United States National Museum of Natural History) were examined. The collection of *C. latrans* was chosen based on an earlier study using the U.S. collection, which reported the presence of a supernumerary molar  $M_4$  in some specimens (Paradiso, 1966). Presence of the supernumerary molar was determined by macroscopic observation. Photographs were taken of the occlusal view of the molar row with scales. Projected areas of  $M_1$ ,  $M_2$ , and  $M_3$  were manually measured using Image J software (NIH, Bethesda, MD, USA). The projected area is defined as molar size, as described by (Kavanagh, Evans & Jernvall, 2007; Asahara, 2013; Asahara, 2014). For specimens of *N. procyonoides*, most data were derived from Asahara (2014). The ratio of  $M_2$  to  $M_1$  size ( $M_2/M_1$ ) and that of  $M_3$  to  $M_1$  size ( $M_3/M_1$ ) were calculated to compare relative sizes among molars. According to the IC model (Kavanagh, Evans & Jernvall, 2007), lower inhibition and higher activation results in higher  $M_2/M_1$  and  $M_3/M_1$  scores, whereas increased inhibition and reduced activation lowers the  $M_2/M_1$  and  $M_3/M_1$  scores.  $M_1$  size and  $M_2/M_1$  and  $M_3/M_1$  scores of individuals with normal dentition, without  $M_3$ , and with  $M_4$  were compared by U-test. Comparisons were performed separately for each species and sample

location (as defined by collection source), with analyses performed using Minitab 14 statistical software (Minitab Inc., PA, USA). For data of the bat-eared fox *Otocyon megalotis* in Fig. 2 is cited from Asahara (2013).

## RESULTS

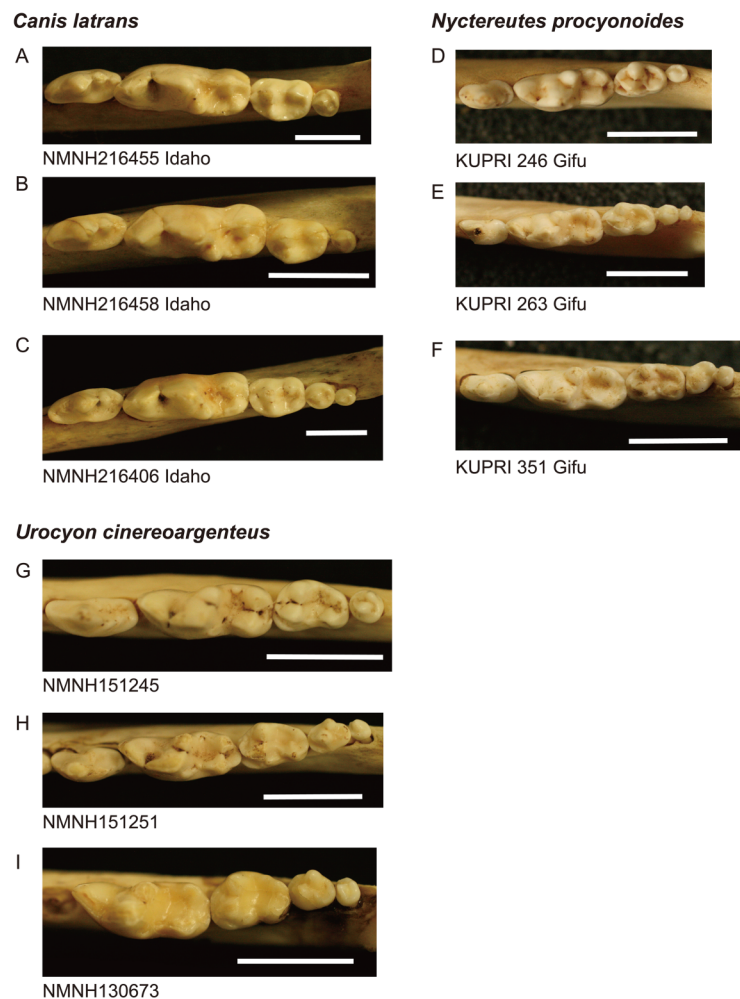

Twelve individuals of *C. latrans* (2.66% of total 451 individuals), four individuals of *N. procyonoides* (2.61% of total 153 individuals), and five individuals of *U. cinereoargenteus* (3.68% of total 136 individuals) possessed an  $M_4$  in the normally aligned molar row (Fig. 1), with occurrences differing according to species and specimen location (Table 1). Data relating to  $M_1$  size and  $M_2/M_1$  and  $M_3/M_1$  scores are presented in Table 1 and Fig. 2. The distribution of specimens with normal dentition represented a typical pattern of interspecific variation among canids (Asahara, 2013) (Fig. 2).  $M_2/M_1$  and  $M_3/M_1$  scores per location and per species are also presented (Figs. 3–5).

No relationship was found between mean  $M_1$  size and presence or absence of  $M_4$  (Table 1). When specimens of all locations were combined, mean  $M_2/M_1$  and  $M_3/M_1$  scores were typically larger in individuals with  $M_4$  than those with normal dentition (without  $M_4$ ), with the exception of  $M_2/M_1$  scores in the Gifu samples of *N. procyonoides* (Table 1). When each location was analyzed separately, no significant difference in  $M_2/M_1$  scores existed between individuals with  $M_4$  and with normal dentition; however, when all locations were pooled, individuals with  $M_4$  showed significantly higher  $M_2/M_1$  scores than individuals with normal dentition in *C. latrans* and *U. cinereoargenteus* (Table 1).  $M_3/M_1$  scores of individuals with  $M_4$  were significantly higher than those of individuals with normal dentition in the Gifu samples of *N. procyonoides* and the New Mexico samples of *U. cinereoargenteus* (Table 1). For the pooled samples of *U. cinereoargenteus*,  $M_3/M_1$  scores of individuals with  $M_4$  were significantly higher than those of individuals with normal dentition (Table 1).

Five individuals of *C. latrans* and thirteen individuals of *N. procyonoides* lacked  $M_3$  (Table 1).  $M_1$  size of individuals without  $M_3$  is significantly larger than that of individuals with normal dentition in *C. latrans*.  $M_2/M_1$  scores of individuals without  $M_3$  were significantly smaller than those of individuals with normal dentition in *N. procyonoides*.

## DISCUSSIONS

The lack of a relationship between  $M_1$  size and individuals with  $M_4$  versus those with normal dentition indicates that absolute  $M_1$  size does not affect the generation of the  $M_4$ . However, individuals with high  $M_2/M_1$  and  $M_3/M_1$  scores (and thus with relatively large  $M_2$ s and  $M_3$ s) did tend to possess a supernumerary molar  $M_4$  (Table 1; Figs. 2–5). While these scores did not differ significantly in most within-location analysis except for  $M_3/M_1$  scores in the Gifu samples of *N. procyonoides* and the New Mexico samples of *U. cinereoargenteus* (Table 1), these results could be affected by the low number of samples that possessed  $M_4$ . To overcome this limitation, analysis of combined sample-locations did establish that  $M_2/M_1$  scores were larger in individuals with  $M_4$  than those with normal dentition in *C. latrans* and *U. cinereoargenteus* (Table 1). These results support the hypothesis that altered inhibition/activation

**Figure 1** Images of lower molar rows ( $P_4$  to  $M_3$  or  $M_4$ ) from the occlusal view in the three species examined. (A–C): coyote *Canis latrans*, (D–F): raccoon dog *Nyctereutes procyonoides*, (G–I): gray fox *Urocyon cinereoargenteus*. Specimens A, B, D, and G possess normal dentition and specimens C, E, F, H, and I possess a supernumerary molar  $M_4$ . Specimen numbers are depicted below the images. dynamics (i.e. lower inhibition and higher activation) is likely to direct the formation of the  $M_4$  in these species.

Geographic variation can affect  $M_2/M_1$  scores of pooled locations, such that locations with higher  $M_4$  incidence simply have a larger  $M_2/M_1$  score. This appears not to be an issue in this study, for two reasons. Firstly, a larger  $M_2/M_1$  score in a location is indicative of a genetic background supporting lower inhibition and higher activation during molar development. Secondly, the ranges of mean  $M_2/M_1$  and  $M_3/M_1$  scores among locations were not larger than the difference between mean scores of individuals possessing or lacking the  $M_4$  (Table 1). The data considered herein supports a causal relationship between inhibition and activation dynamics and the occurrence of  $M_4$ .

While the existence of  $M_4$  correlates with high  $M_2/M_1$  and  $M_3/M_1$  scores, there were many individuals that exhibited high  $M_2/M_1$  or  $M_3/M_1$  scores but whose mandible

did not possess  $M_4$  (Figs. 1–5), indicating that inhibition/activation dynamics are likely to be only one of the causes of generating an extra molar. This interpretation is supported by the experimental suppression of inhibition in a mouse model resulting in only one case of the appearance of an extra molar (Kavanagh, Evans & Jernvall, 2007). Acquisition of  $M_4$  is rare during evolution of placental mammals (Sillero-Zubiri, 2009; Ungar, 2010), and it is logical that several barriers to  $M_4$  generation exist. Furthermore, occasional occurrence of  $M_4$ , albeit at a low rate, suggests that canids may possibly possess a genetic background that favors the generation of the  $M_4$ , and this may explain the evolution of an additional molar in the bat-eared fox *O. megalotis*.

$M_2/M_1$  scores were larger in individuals without  $M_3$  than those with normal dentition in *N. procyonoides* (Table 1). The result accords with the proposed relationship between

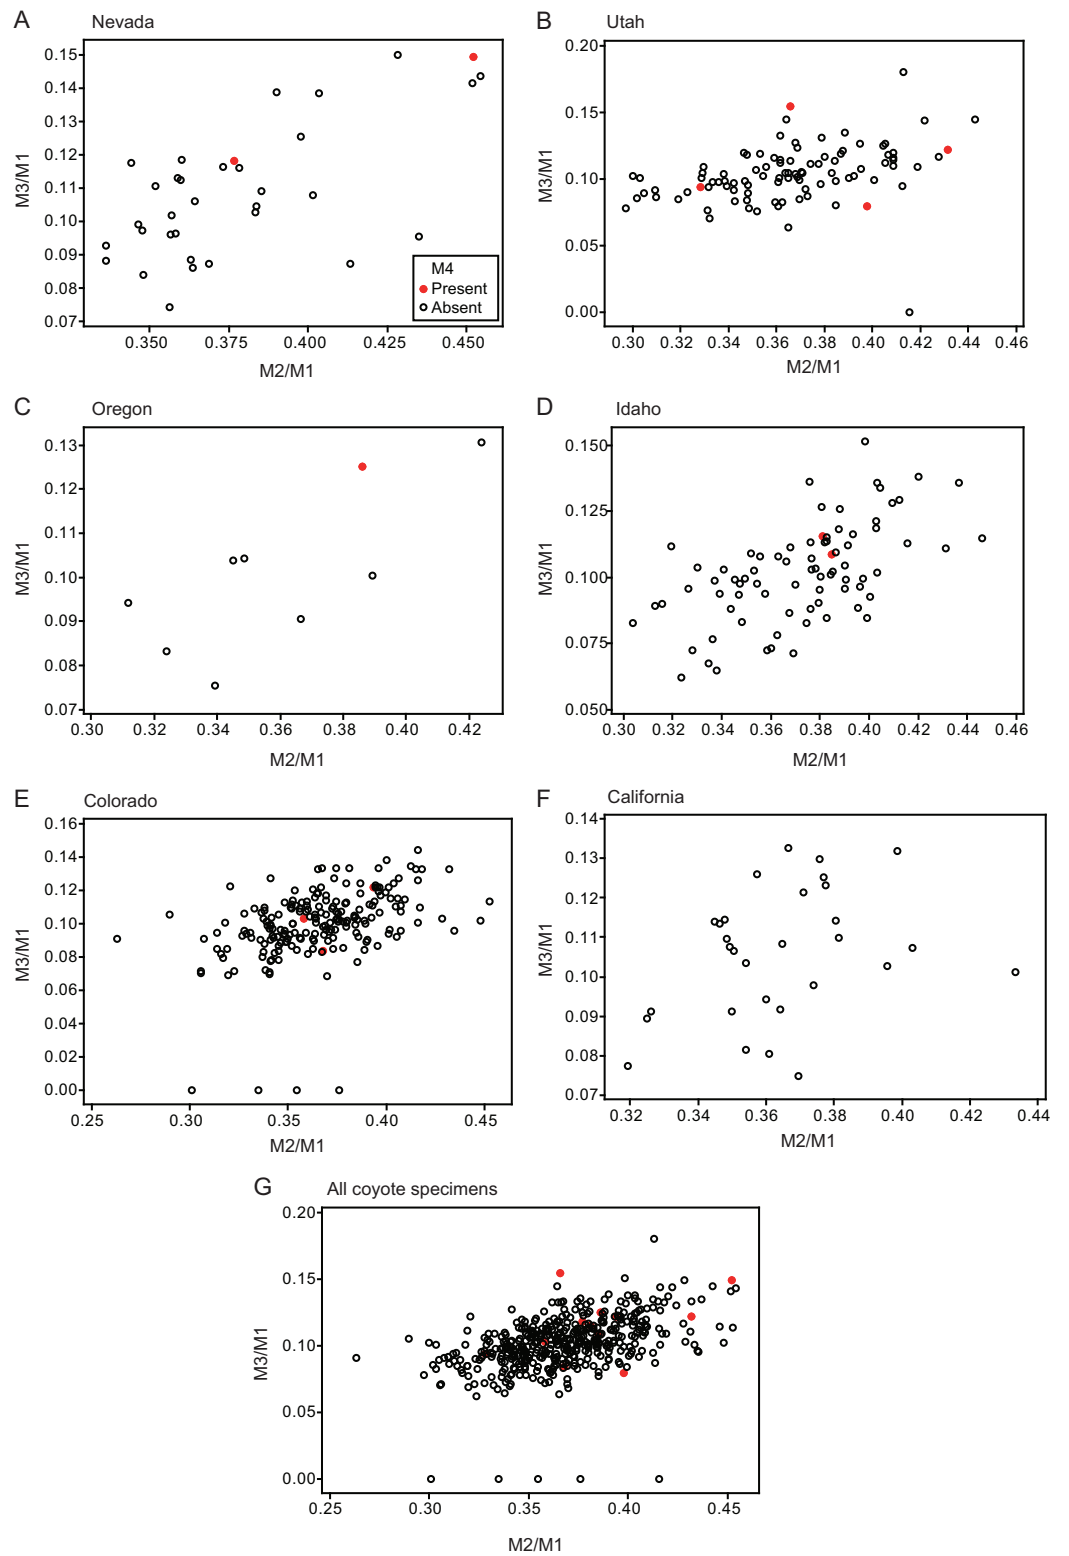

**Figure 2** Bivariate plots of  $M_2/M_1$  and  $M_3/M_1$  scores of all specimens examined in this study and of the bat-eared fox *Otocyon megalotis* (Asahara, 2013). Specimens that do and do not possess  $M_4$  are depicted separately. The blue line indicates the molar ratio predicted by the inhibitory cascade model, as proposed by Kavanagh, Evans & Jernvall (2007), indicating variability found in molars of different murine species and experimentally generated mice. The red line indicates the trend of the molar ratio among canid species (Asahara, 2013).

dental anomalies ( $M_3$  loss) and the IC model reported by Asahara (2013). Significant differences in  $M_1$  size found in *C. latrans* (Table 1) could be affected by the low number of samples including a large individual that lacked  $M_3$ .

Consistent with Paradiso (1966), this study found that the presence or absence of  $M_4$  differed among locations of *C. latrans*. Furthermore, Gisburne & Feldhamer (2005) reported that  $M_4$  was not observed among 510 specimens of Illinois *U. cinereoargenteus*, contrasting with the finding from this study of the presence of  $M_4$  in a low proportion of Arizona and New Mexico gray foxes. Most studies of raccoon dog (*N. procyonoides*) have reported no  $M_4$  molar in Japanese samples (Hata, 1972; Harada et al., 1989; Asahi & Mori, 1980; Nozaki, 1984; collectively 664 individuals), with a notable exception published by Machida & Saito (1986), who reported an  $M_4$  in just one of 137 raccoon dogs from Saitama prefecture in Japan. Therefore, the presence of  $M_4$  in the three canid species examined in this study is considered a rare anomaly.

Asahara (2013) and Asahara et al. (2016) reported that the relative molar size was reflective of the diet among species of canids. The more carnivorous canid species (such as *Canis lupus*) possess low  $M_2/M_1$  scores and the more omnivorous species (such as *N. procyonoides* or *U. cinereoargenteus*) have higher scores (Asahara, 2013; Asahara et al., 2016). In addition,

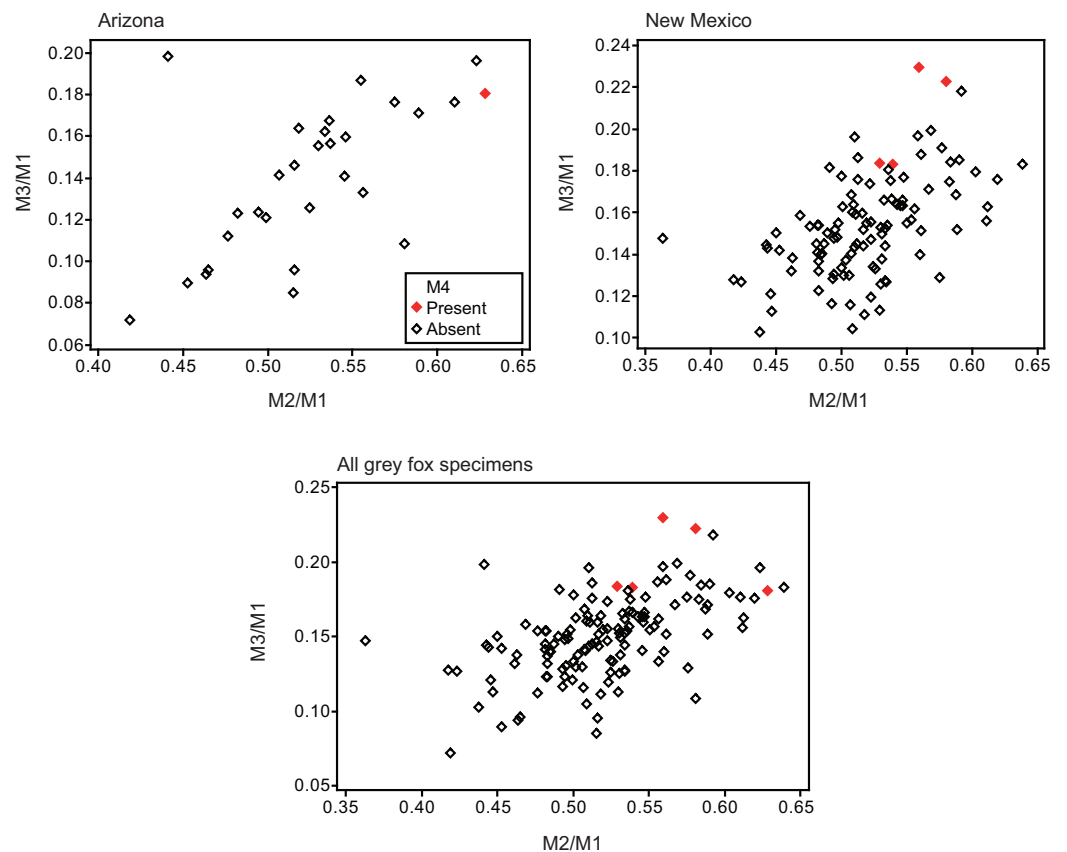

**Figure 3** Bivariate plots of  $M_2/M_1$  and  $M_3/M_1$  scores among specimens of coyote *Canis latrans*. Specimens possessing  $M_4$  (red circle) and those lacking  $M_4$  (black circle) are shown separately.

**Figure 4** Bivariate plots of  $M_2/M_1$  and  $M_3/M_1$  scores among specimens of raccoon dog *Nyctereutes procyonoides*. Specimens possessing  $M_4$  (red square) and those lacking  $M_4$  (black square) are shown separately.

**Figure 5** Bivariate plots of  $M_2/M_1$  and  $M_3/M_1$  scores among specimens of gray fox *Urocyon cinereoargenteus*. Specimens possessing  $M_4$  (red diamond) and those lacking  $M_4$  (black diamond) were shown separately.

the insectivorous hoary fox *Lycalopex vetulus* has higher  $M_2/M_1$  and  $M_3/M_1$  scores than almost all other omnivorous species, and the insectivorous bat-eared fox *O. megalotis* has higher  $M_2/M_1$  and  $M_3/M_1$  scores than all other canids, indicating very low inhibition and high activation during molar development (Asahara, 2013). According to this pattern, the evolution of the insectivorous diet is associated with molars that are of more equal size (between  $M_1$ ,  $M_2$ , and  $M_3$ ) than the carnivorous or omnivorous species, with higher  $M_2/M_1$  and  $M_3/M_1$  scores reflecting low inhibition and high activation during molar development. The present study is consistent with the hypothesis that low inhibition and high activation is a cause of  $M_4$  generation. Therefore,  $M_4$  is considered to be an adaptive trait providing a larger total occlusal surface area to enable the canid to digest a large amount of insects, as discussed by Asahara (2013) and Asahara et al. (2016). It is hypothesized that the ancestral species began to consume an insectivorous diet, and it followed that a pattern of low inhibition and high activation during molar development evolved to generate more equally sized molars (between  $M_1$ ,  $M_2$ , and  $M_3$ ) than its ancestor, providing an evolutionary force supporting this adaptation to the insectivorous diet. Then, the inhibition/activation pattern generates  $M_4$  by chance.  $M_4$  is also an adaptive trait for insectivorous diet providing larger occlusal surface area and greater grinding function, therefore, presence of  $M_4$  is naturally selected and fixed in the ancestral lineage of the bat-eared fox. While no fossil canid species has been found to possess an  $M_4$ , several cases of a small supernumerary  $M^3$  has been reported in an individual of the *Prototocyon* genus (Petter, 1964; Petter, 1973), which may be closely related to (or belong to) *Otocyon* (Van Valen, 1964; Petter, 1964; Petter, 1973; Wang & Tedford, 2008; Tedford, Wang & Taylor, 2009; Werdelin & Peigne, 2010). This supports the argument that this genus was a transitional stage in which molar number increased. Further discoveries from the fossil record will be important in revealing the evolutionary history of the fourth molar.

## CONCLUSIONS

The presence of a supernumerary molar  $M_4$  observed in several canid species is influenced by low inhibition and high activation during molar development, with the presence of  $M_4$  in the bat-eared fox *O. megalotis* originating from low inhibition and high activation due to evolutionary pressure relating to an insectivorous diet.

## ACKNOWLEDGEMENTS

I thank E. Langan (the United States National Museum of Natural History) for arranging specimens.

## ADDITIONAL INFORMATION AND DECLARATIONS

### Funding

This study was financially supported by Grant-in-Aid from Japan Society for the Promotion of Science (11J01149 and 16K18601). The funders had no role in study design, data collection and analysis, decision to publish, or preparation of the manuscript.

## Grant Disclosures

The following grant information was disclosed by the authors:  
Japan Society for the Promotion of Science: 11J01149 and 16K18601.

## Competing Interests

The author declares that they have no competing interests.

## Author Contributions

- Masakazu Asahara conceived and designed the experiments, performed the experiments, analyzed the data, wrote the paper, prepared figures and/or tables.

## Animal Ethics

The following information was supplied relating to ethical approvals (i.e., approving body and any reference numbers):

Materials in this study are skull specimens that have been deposited in museums. Therefore ethical approval is not applicable.

## Data Deposition

The following information was supplied regarding data availability:

The raw data has been supplied as [Supplemental Dataset Files](#).

## Supplemental Information

Supplemental information for this article can be found online at <http://dx.doi.org/10.7717/peerj.2689#supplemental-information>.
