Abstract: Epistaxis is the commonest emergency in otorhinolaryngology. Over the last decade endoscopic sphenopalatine artery (SPA) ligation has become a popular treatment option for posterior epistaxis and has been shown to be the most effective and cost-efficient definitive treatment for posterior epistaxis. SPA ligation is usually performed under general anesthesia. The majority of epistaxis patients are elderly, frail and have multiple medical conditions. These patients are therefore not always amenable to general anesthesia. In this article we describe two cases where posterior epistaxis was successfully treated with sphenopalatine artery ligation under local anesthesia and should be considered suitable for patients with severe posterior epistaxis who are not fit for a general anesthetic.

Keywords: epistaxis, sphenopalatine artery ligation, local anesthesia

Case report I

A 44-year-old man was involved in a car accident and sustained a head injury in addition to significant injuries to his face and left eye. He reportedly lost consciousness for five minutes immediately after the accident, although he was fully conscious when the paramedics arrived at the scene of the accident. Shortly after arriving at the hospital he became confused and complained of weakness in his left upper limb.

An urgent head computerized tomography (CT) scan was performed and showed no significant brain injury. However, the scan did reveal a fracture of the left orbital floor together with multiple undisplaced nasal fractures (Figure 1). A diagnosis of a non-dominant hemispheric stroke was made and a magnetic resonance imaging (MRI) and magnetic resonance angiography (MRA) were requested. These scans revealed global ischemia of the right cerebral hemisphere as well as dissection of the right internal carotid artery (Figure 2). Because of the high risk of thrombus formation the patient was started on intravenous heparin. Seven days later he developed severe left sided epistaxis requiring posterior nasal packing. His hemoglobin dropped from 13.5 to 8 g/dL and in view of further possible life threatening epistaxis the decision was made to discontinue his heparin. As a result the main concern became that he was again at significant risk of a further stroke and heparin was required to prevent this. So that we could re-start his heparin safely it was decided that he needed definitive treatment of his epistaxis. The decision was therefore made to perform both sphenopalatine artery (SPA) and anterior ethmoidal artery ligation.

After discussion with the anesthetist there was concern that this patient was at significant risk of developing a further cerebrovascular accident (CVA) if he

were to undergo a general anesthetic. Embolization was a treatment option for the SPA although not for the anterior ethmoidal artery as this is part of the internal carotid artery system and therefore poses a significant risk of causing a CVA or embolus in the ophthalmic artery with potential visual loss. It was therefore decided that the safest option was to perform the surgery under local anesthesia. The left anterior ethmoidal artery was identified and ligated without any difficulty via the usual medial canthus incision (Lynch incision). The left SPA ligation was performed after preparing the nose with topical anesthetic and decongestant spray, a greater palatine foramen block and local anesthetic infiltration into the lateral wall of the middle meatus.

The greater palatine foramen block was performed in the following way. The foramen was identified by trans-oral palpation of the hard palate in line with the third molar tooth (Figure 3). A 25G needle bent to 45 degrees 2.5 cm from the tip was used to inject 2 mL of lidocaine (2% with adrenaline 1:80 000) solution into the foramen. Immediate blanching of the hemi-palate confirmed accurate placement of the needle and subsequent vasoconstriction.

Infiltration of the lateral nasal wall of the middle meatus, with 2 mL of the same solution mentioned above, was performed under endoscopic guidance. An incision was made in the lateral wall of the medial meatus 1 cm anterior to the posterior attachment of the middle turbinate. A mucosal flap was raised and the ethmoidal crest and SPA identified as it exits the sphenopalatine foramen. The artery was ligated using metal clips. The mucosal flap was replaced and no nasal packs were inserted after surgery.

Figure 2 A magnetic resonance angiography (MRA) of patient 1, which reveals global ischemia of the right cerebral hemisphere as well as dissection of the right internal carotid artery (circled).

Intravenous (IV) heparin was re-commenced immediately after the procedure. The patient did not have any further bleeding and made good progress with excellent functional recovery of his upper limb. He was subsequently started on warfarin for a further 6 months to prevent further embolic episodes.

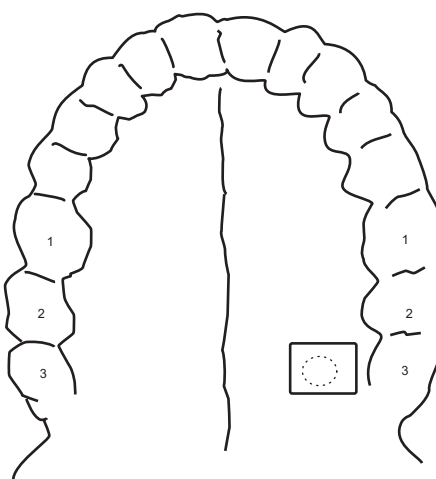

Figure 3 Schematic drawing demonstrating the position of the left greater palatine foramen in line with the third upper molar tooth on the left hand side.

Case report 2

A 20-year-old male patient was referred to the otolaryngologist with a history of recurrent right-sided posterior epistaxis. He was a known, oxygen dependant, cystic fibrosis patient awaiting a lung transplant. He required posterior nasal packs on several occasions to control his epistaxis, he found this very troublesome as it prevented him from administering oxygen via a nasal prong and forced him to use a facemask.

After discussion with the patient and the success of the first case it was decided to perform a SPA ligation under local anesthetic to hopefully prevent further epistaxis. The procedure was performed in an identical fashion to the first case. The patient tolerated the procedure very well and again no nasal packs were inserted at the end of the procedure. He has not had any further bleeding to date – 3 months.

Discussion

Epistaxis is a common condition with an incidence of 108/100 000 population, per year.¹ It is the most common emergency in otorhinolaryngology. The majority of epistaxis will originate from the anterior septum and will be treated with conservative measures.

Posterior epistaxis is usually more severe and often will require posterior nasal packing. Posterior nasal packs including balloon tamponade will fail in 26% to 52% of cases,^{2,3} and the next management step will be either surgery or embolization.

Embolization services will only be available at large centers. Traditional surgical options include ligation of one or more of the following arteries: external carotid, internal maxillary and anterior ethmoidal artery. More recently endoscopic SPA ligation has become a popular treatment option for posterior epistaxis. Some authors advocate bilateral SPA ligation with or without anterior ethmoidal artery ligation for the treatment of intractable posterior epistaxis that has failed conventional nasal packing.⁴

Two published studies have reported that surgical intervention was more cost effective than medical treatment or arterial embolization.^{5,6} Endoscopic SPA ligation is the most effective and cost efficient treatment for posterior epistaxis.⁷ In a study involving 127 patients epistaxis was controlled in 98% of cases.⁸

Microsurgical ligation of the SPA was first described by Prades in the 1970s⁹ and endoscopic SPA ligation was first described in 1992 by Budrovich and Saetti.¹⁰ The majority of large studies report success rates of around 90%.¹¹ and a better understanding of the anatomy of the SPA through

recent articles should improve the efficacy of the procedure performed. Lee reported that the SPA will divide into 2 to 4 branches before exiting the sphenopalatine foramen. The majority of cases (76%) will have only two branches.¹² In 12% of cases the septal branch of the SPA will emerge from a separate foramen.¹³ This means that the surgeon should actively look for further branches after identifying and ligating the first identifiable branch. Complications are minor and include increased nasal crusting and palatal numbness.¹⁴

The majority of epistaxis patients are elderly, frail and have multiple medical conditions.¹⁵ These patients are therefore not always amenable to general anesthesia. Furthermore patients with significant coronary atherosclerosis will not be able to tolerate hypotensive anesthesia in an attempt to reduce bleeding and improve the surgical field. It would therefore be ideal if endoscopic surgery for posterior epistaxis can be performed under local anesthesia and that local bleeding can be controlled without inducing systemic hypotension.

Pterygopalatine fossa infiltration with vasoconstrictors and local anesthesia through the greater palatine foramen has been described in the literature. Surgical access to the pterygopalatine fossa was described as early as 1935 when Averbukh and colleagues described a transpalatine technique to gain access to the sphenopalatine ganglion as well as the second part of the trigeminal nerve for the treatment of trigeminal neuralgia. Furthermore they concluded that the surgery can be performed under local anesthesia.¹⁶

Vasoconstrictors infiltrated into this space will target the third part of the maxillary artery as it enters the pterygopalatine fossa. This will cause vasospasm of the maxillary artery and decrease blood flow into the sphenopalatine artery with subsequent decrease in blood supply to the nasal cavity mucosa. Infiltration with vasoconstrictor solutions into the greater palatine foramen have been shown to significantly reduce intra-operative bleeding during endoscopic sinus surgery and septorhinoplasty and help control posterior epistaxis.¹⁷⁻¹⁹

Sensory innervation of the lateral wall of the nasal cavity is supplied by the posterior nasal branches of the maxillary nerve as well as the nasopalatine nerve (itself a branch of the maxillary nerve). The septum is supplied by the nasociliary nerve (a branch of the ophthalmic branch of the trigeminal nerve) and the nasopalatine nerve. Both the nasopalatine nerve and the posterior nasal branches of the maxillary nerve can be reached in the pterygopalatine fossa. This means that the lateral wall of the nasal cavity as well as the posterior aspect of the septum can be successfully

anesthetized with local anesthetic infiltration of the pterygopalatine fossa via the greater palatine foramen.

Local anesthetic infiltration via this route has been used successfully to provide regional anesthesia for dental procedures as well as improve pain associated with removal of nasal packs following surgery.^{20,21} Cadaver based anatomy studies by Douglas and Wormald suggested that a 25-G needle, bent at 45 degrees, 25 mm from the tip will ensure optimal pterygopalatine fossa infiltration.²² This will ensure maximal vasospasm of the maxillary artery as well as a nerve block of the terminal branches of the maxillary nerve, with minimal risk to the orbital contents and infraorbital nerve.

Our experience with these two cases is that endoscopic SPA ligation is possible under local anesthesia and should be considered in patients with severe posterior epistaxis for whom a general anesthetic is unsuitable.
