ABSTRACT: Inorganic cubic rubidium−lead-halide perovskites have attracted considerable attention owing to their structural, electronic, and unique optical properties. In this study, novel rubidium–lead-bromide (RbPbBr3)-based hybrid perovskite solar cells (HPSCs) with several high-band-gap chalcogenide electron transport layers (ETLs) of  $In_2S_3$ ,  $WS_2$ , and  $SnS_2$  were studied by density functional theory (DFT) and using the SCAPS-1D simulator. Initially, the band gap and optical performance were computed using DFT, and these results were utilized for the first time in the SCAPS-1D simulator. Furthermore, the impact of different major influencing parameters, that is, the thickness of the layer, bulk defect density, doping concentration, and defect density of interfaces, including the working temperature, were also investigated and unveiled. Further, a study on an optimized device with the most potential ETL  $(SnS_2)$  layer was performed systematically. Finally, a comparative study of different reported heterostructures was performed to explore

the benchmark of the most recent efficient RbPbBr<sub>3</sub>-based photovoltaics. The highest power conversion efficiency (PCE) was 29.75% for the SnS<sub>2</sub> ETL with *V*<sub>oc</sub> of 0.9789 V, *J*<sub>sc</sub> of 34.57863 mA cm<sup>−2</sup>, and fill factor (FF) of 87.91%, while the PCEs of 21.15 and 24.57% were obtained for In<sub>2</sub>S<sub>3</sub> and WS<sub>2</sub> ETLs, respectively. The electron–hole generation, recombination rates, and quantum efficiency (QE) characteristics were also investigated in detail. Thus, the  $SnS<sub>2</sub> ETL$  shows strong potential for use in RbPbBr<sub>3</sub>-based hybrid perovskite high-performance photovoltaic devices.

# **1. INTRODUCTION**

A significant breakthrough in the field of photovoltaics has been made possible by the development of perovskite materials as possible replacements for efficient solar cell technology. Perovskite from the  $A_3$ MX<sub>3</sub> (where A is a larger size inorganic cation, M is a smaller metal cation, and X is an anion) group has lately emerged as a standout candidate, revealing remarkable characteristics that make it very well suited for solar energy conversion applications.<sup>[1](#page-10-0)−[6](#page-10-0)</sup> On the other hand, recently,  $ABX_3$  (A and B are cations, and "X" is an anion)-type perovskite is also used for applications involving the conversion of solar energy. Perovskites are ideal for a variety of applications, including photovoltaics, optoelectronics, catalysis, and energy storage due to their exceptional properties, which include high electron and ion mobility, tunable band gap, and efficient light absorption.<sup>[7](#page-10-0)-[10](#page-11-0)</sup> The scientific community is very much interested in perovskite materials because they may be used to achieve an outstanding performance of PV (photovoltaic) solar cells.<sup>11−[15](#page-11-0)</sup> Perovskitebased organic−inorganic hybrid solar cells (HPSCs), which have high light absorption, low defect density, long chargecarrier lifespan, high charge-carrier flexibility, and low

stimulation binding energies, are significantly advancing device design and element control.<sup>[16](#page-11-0)−[20](#page-11-0)</sup> These organic cations' volatility and thermal instability represent the biggest interruption to their wide-ranging commercial applications. $21$ However, inorganic  $RbPbBr<sub>3</sub>$  can significantly speed up advancing the fabrication of perovskite hybrid solar panels (cells) owing to their exceptional electronic and optical properties.<sup>[22](#page-11-0)</sup> RbPbBr<sub>3</sub> has a suitable band gap (~1.31 eV) and a high absorption coefficient of  $\sim 10^5$  cm<sup>-1</sup> with enhanced thermal stabilities and structurally inflexible phases at room temperature.[23](#page-11-0)−[26](#page-11-0) A suitable choice of efficient electron transport layers (ETLs), an insertion of favorable element ions into the RbPbBr<sub>3</sub> host lattices, is an efficient approach to obtaining improved PV performance.[27](#page-11-0)−[29](#page-11-0) The ETL offers the

Figure 1. (a) Crystal structure of RbPbBr<sub>3</sub>, (b) device structure, (c) energy band diagram with the In<sub>2</sub>S<sub>3</sub> ETL, (d) energy band diagram with the  $WS_2$  ETL, (e) energy band diagram with the SnS<sub>2</sub> ETL, and (f) the energy band alignment with the optimized structure (Al/FTO/SnS<sub>2</sub>/RbPbBr<sub>3</sub>/ Au).

easiest pathway for transporting electrons through the perovskite surface to an electrode preventing the recombination of electrons and holes notably and ensuring loss-free passing of incident solar spectra.<sup>[30](#page-11-0),[31](#page-11-0)</sup> Several solar cell architectures have been developed and put forth to date; however, when compared to different RbPbBr<sub>3</sub>-heterostructure variants, their PCEs are found to be as high as expected. $32,33$ The two-dimensional (2D) chalcogenide sulfur (S)-based ETLs of  $In_2S_3$ , WS<sub>2</sub>, and  $SnS_2$  have been found to be promising for  $RbPbBr_3$  heterostructure photovoltaics. Among them,  $SnS_2$ , with a band gap of up to 1.6−2.24 eV and an absorption coefficient of  $\sim 10^5$  cm<sup>-1</sup>, appears to be one of the best potential materials as an ETL for fabricating high-efficiency solar cells, retaining the large ability for charge transmission as well as accumulation with a well-aligned band structure. The wide-band-gap  $SnS<sub>2</sub>$  has also shown high electron flexibility

and rigidity with the visible wavelengths of the light spectrum, thereby efficiently transporting carriers from the photoactive layers to the electrode, resulting in boosting the overall device performance.<sup>3</sup>

In this study, RbPbBr<sub>3</sub>-based hybrid perovskite solar cells (HPSCs) with several chalcogenide ETLs of  $In_2S_3$ , WS<sub>2</sub>, and  $SnS<sub>2</sub>$  have been studied. Initially, the impact of different major influencing parameters, namely, the layer thickness, bulk defect density, doping concentration, and interface defect density, including the working temperature, were investigated and unveiled. After that, a systematic study of an optimized device with the most potential ETL  $(SnS_2)$  layer was performed. Finally, a comparative study on different reported heterostructures was performed to design the most recently developed efficient RbPbBr<sub>3</sub>-based photovoltaics. However, the  $SnS<sub>2</sub>$  ETL is not only suitable for Rb-based PSC devices but can also be used in many other types of PSCs with outstanding performance, such as CsPbI<sub>3</sub>, FAPbI<sub>3</sub>, MAPbI<sub>3</sub>,<br>EAMAPbI\_Sr SbI\_Sr PI\_and Ca NI <sup>[35](#page-11-0)–[39](#page-11-0)</sup> FAMAPbI<sub>3</sub>, Sr<sub>3</sub>SbI<sub>3</sub>, Sr<sub>3</sub>PI<sub>3</sub>, and Ca<sub>3</sub>NI<sub>3</sub><sup>3</sup>

# **2. CONSTRUCTION AND SIMULATION METHODOLOGY**

A one-dimensional solar cell capacitance simulator (SCAPS) application was used for the simulation to examine the proposed Al/FTO/ETLs  $(In_2S_3, WS_2, or SnS_2)/RbPbBr_3/Au$ photovoltaic cells, assigned as Devices I  $(SnS_2)$ , II  $(WS_2)$ , and III  $(In_2S_3)$ , respectively. At the Electronic and Information Systems Department of the University of Ghent, Belgium, SCAPS-1D software was invented. By resolving fundamental equations, continuity equations for electrons and holes, and electrostatic potential equations under steady-state conditions, both structures were anticipated and analyzed systemati-cally.<sup>[40,41](#page-12-0)</sup> [Figure1a](#page-1-0) shows the crystal structure of an inorganic cubic RbPbBr<sub>3</sub> perovskite. [Figure](#page-1-0) 1b shows the symmetric structures of devices I−III at a given time. The PV cell consisted of a p-type absorber layer, a highly doped n-type ETL  $(In_2S_3, WS_2, or SnS_2)$  layer with an FTO window layer and an Au back-metal electrode. [Figure1](#page-1-0)c−e shows the energy band diagram (EBD) with an illustration of the carrier dynamics for the corresponding devices, and [Figure1f](#page-1-0) shows the energy band alignment with the optimized structure of (Al/FTO/SnS2/RbPbBr3/Au). The electron−hole pair formation within the device is confirmed by the specific positions of quasi-Fermi states Fn and Fp under illumination. The generation of electron−hole pairs within the device is confirmed by the offset between the absorber VB and CB. The difference in the work function (WF) between the absorber and transmission layers is the cause of the observed offset. At the absorber/ETL interface, the integrated voltage and related fields of electricity assist in the separation of the generated light.

#### **3. RESULTS AND DISCUSSION**

**3.1. Band Structure.** The band structure of the RbPbBr<sub>3</sub> perovskite with the Brillouin zone path Γ−*X*−*M*−*R*−Γ is shown in Figure 2. Using the GGA-PBE function, we obtained a band gap of 1.31 eV at the *R*-point in Figure 2. The GGA-PBE function produces more reasonable results. We indicated the energy levels from −5 to +5 eV, and at point *R*, the material's band structure reveals a direct gap with a value of 1.31 eV, with the vertical line representing the Fermi level  $(E_f)$ = 0 eV. The material's direct band gap is caused by an unusual

Figure 2. Band structure of the  $RbPbBr<sub>3</sub>$  perovskite.

occurrence where the highest energy level of the valence band coincides precisely with the lowest energy level of the conduction band at a specific symmetry point (*R*). The material's high absorption coefficient is due to this straight band gap.

**3.2. Optical Properties.** [Figure](#page-3-0) 3a,b illustrates the optical characteristics of the RbPbBr<sub>3</sub> perovskite, including the optical absorption and the imaginary and real components of the dielectric function. The optical absorption coefficient is an essential indicator of how well a material is able to absorb light energy and offers compelling evidence in favor of solar efficiency.[39,](#page-11-0)[42](#page-12-0)−[44](#page-12-0) The profile of the optical absorption coefficient displays traits that are reminiscent of the imaginary component of the dielectric constant for all configurations. The greatest peak in the optical absorption spectrum can be found for the  $RbPbBr<sub>3</sub>$  perovskite structures in the visible region. [Figure](#page-3-0) 3a demonstrates the absorption coefficient of the  $RbPbBr<sub>3</sub>$  perovskite structures as a function of the photon energy. The optical properties of  $RbPbBr<sub>3</sub>$  that have been studied here show a good fit with the previously reported results.[30](#page-11-0),[45](#page-12-0)

The complex dielectric function, which is energy- or frequency-dependent, is transformed using the Kramers− Kronig eq 1

$$
\varepsilon(\omega) = \varepsilon_1(\omega) + i\varepsilon_2(\omega) \tag{1}
$$

where the real part is defined by  $\varepsilon_1(\omega)$  and the imaginary part is defined by  $i\varepsilon_2(\omega)$ .

The real portion of the dielectric constant can be used to calculate the dispersion effects and polarization. The zerofrequency limit,  $\varepsilon_1(0)$ , which corresponds to the electronic component of the real dielectric function, is the best essential quantity in the real part  $\varepsilon_1(\omega)$ . For cubic RbPbBr<sub>3</sub>, the computed  $\varepsilon_1(0)$  value is 5.8. The values of the real part  $\varepsilon_1(\omega)$ began to increase from  $\varepsilon_1(0)$ , first reaching the highest value, after which they decreased and produced many peaks. In general, large band gap materials have a lower peak dielectric constant value than low band gap materials. The imaginary component of the dielectric function is a crucial property for assessing the optical absorption and the ability of crystal structures to store energy from neutral charge excitations. Furthermore, the imaginary portion  $\varepsilon_2(\omega)$  is closely tied to the system's band structure. The  $\varepsilon_2(\omega)$  values of RbPbBr<sub>3</sub> suggest a broad absorption spectrum. The transition of carriers from the VB to the CB is shown by the peaks of the imaginary component of the dielectric constant.

[Table](#page-3-0) 1 demonstrates simulation parameters for the active materials of FTO,  $In_2S_3$ , WS<sub>2</sub>, SnS<sub>2</sub>, and RbPbBr<sub>3</sub>, which were

<span id="page-3-0"></span>

Figure 3. (a) Optical absorption and (b) the imaginary and real parts of the dielectric function.

collected from the previous notable literature, and the realistic thermal velocity of the electrons and holes were fixed at  $10<sup>7</sup>$  cm  $s^{-1}$ <sup>[23,30,34](#page-11-0),[46,47](#page-12-0)</sup> The back and front electrodes were made of gold (Au) and aluminum (Al) having WFs of 5.37 eV (110) and 4.2 eV (100), respectively. Table 2 lists the parameters of the absorber/ETL interface used for each of the three proposed photovoltaic devices.

# Table 2. Data for Interface Parameters Used in the RbPbBr3-Based Solar Cells

**3.3. Optimization of Thickness and Charge-Carrier Concentration of the Absorber Layer.** [Figure](#page-4-0) 4a shows the impact of variation of the absorber layer thickness of 100− 2000 nm to obtain the optimized performance of the proposed devices while keeping the other parameters unchanged, as demonstrated in Table 2. The carrier generation as well as substantial recombination rates increase with increasing thickness of the absorber layer noticeably. With increasing

absorber layer thickness, the open-circuit voltage and *V*oc of the PSC increased for every configuration of the three different ETLs. A value of 0.95 V was obtained within device I for the  $SnS<sub>2</sub>$  configuration, though the increment rate was high (from 0.69 to 0.84 V) for device III  $(In_2S_3)$ . Similarly, the shortcircuit current  $(J_{\rm sc})$  increased with increasing thickness of the absorber layer, owing to improved spectral absorption, especially at longer wavelengths. The *J<sub>sc</sub>* increased from 12 to 32.77 mA cm<sup>−</sup><sup>2</sup> for device III, from 17.025 to 35.14 mA cm<sup>−</sup><sup>2</sup> for device I, and from 19.34 to 35.12 mA cm<sup>−</sup><sup>2</sup> for device II. The saturated spectral absorption and domination of charge-carrier recombination at a thick absorber layer of ≥1000 nm for each of the three configurations. These changes in  $V_{\text{oc}}$  and  $J_{\text{sc}}$  are consistent with those reported in previous articles.<sup>[50](#page-12-0)−[52](#page-12-0)</sup> The cell fill factor (FF) is almost unchanged at 87 and 79% for devices I and II, respectively, while it increases from 68 to 85% for device III with increasing absorber layer thickness. A PSC usually operates at its maximum value when the absorber layer thickness and charge-carrier diffusion length are equal.

A higher number of photons are absorbed in a thick absorber layer; however, the rate of recombination also increases simultaneously. Thus, a proper equilibrium is essential within the absorption of light and separation of bearers to obtain high performance.<sup>[53](#page-12-0)–[55](#page-12-0)</sup> With a series of simulations, the  $V_{\text{oc}}$  values of 0.951, 0.897, and 0.8267 V,  $J_{\text{sc}}$ values of 34.55, 34.5548, and 30.22 mA cm<sup>−</sup><sup>2</sup> , FF values of 87.49, 79.05, and 84.46%, and consequently, the PCE values of

<span id="page-4-0"></span>

**Figure 4.** Impact of variation in (a) absorber layer thickness and (b) doping density of the absorber on the PV parameters  $V_{\alpha\alpha}$   $J_{\rm sc}$ , FF, and PCE.

28.75, 24.56, and 21.11%, were obtained at an optimal RbPbBr<sub>3</sub> absorber layer thickness of ~1000 nm for the SnS<sub>2</sub>,  $WS_2$  and  $In_2S_3$  ETL configurations, respectively.

Figure 4b illustrates the changes in the electronic parameters of  $V_{\text{o}c}$ ,  $J_{\text{sc}}$ , FF, and PCE with the acceptor-doping density  $(N_A)$ of the RbPbBr<sub>3</sub> absorber from 10<sup>9</sup> to 10<sup>18</sup> cm<sup>-3</sup> for the three proposed configurations. During optimization, the *V*oc of the PSC remained almost unchanged up to an  $N_A$  of  $10^{14}$  cm<sup>-3</sup>. At higher  $N_A$ , i.e., beyond  $N_A$  of  $10^{14}$  cm<sup>-3</sup>, the  $V_{\text{oc}}$  tends to increase, which leads to a lower shift in the Fermi energy level of the hole, resulting in improved built-in potential.<sup>[56](#page-12-0)</sup> The  $V_{\text{oc}}$ reaches up to 0.97 and 0.90 V for devices I and II, while it is 0.88 V for device III with a relatively higher rate of change. Similar behavior was also observed for FF with noticeable (2− 3%) improvement, reaching almost saturated values of 87.49, 79.23, and 84.46% for the  $SnS_2$ ,  $WS_2$ , and  $In_2S_3$  ETL  $\text{configurations, respectively, at a } N_A \text{ of } 10^{17} \text{ cm}^{-3}, \text{ as}$ summarized in Table 3 These results were consistent with those of previous reports.<sup>[57,58](#page-12-0)</sup>

Table 3. PV Characteristics of Solar Cells Based on  $RbPbBr<sub>3</sub>$  are Compared with Different ETLs

parameters	SnS <sub>2</sub>	WS,	$In_2S_3$
thickness (nm)	10	10	10
$V_{\Omega C}$ (V)	0.951	0.8967	0.8267
$J_{\rm SC}$ (mA cm <sup>-2</sup> )	34.5542	34.5466	30.22143
FF(%)	87.49	79.23	84.46
PCE $(\% )$	28.75	24.56	21.1

**3.4. Optimization Thickness of Various ETLs.** [Figure](#page-5-0) 5 shows the effects of  $SnS_2$ ,  $WS_2$ , and  $In_2S_3$  ETL thicknesses on the PV parameters in the range of 10−500 nm, keeping the remaining adjusted parameters unchanged, as demonstrated in the aforementioned tables. An insignificant change in the PV parameters was observed when varying the ETL thicknesses in the range of 10−500 nm.

Consequently,  $V_{\text{o}q}$ ,  $J_{\text{s}q}$ , FF, and PCE changed from 0.95 to 0.9498 V, 34.55 to 34.6993 mA cm<sup>−</sup><sup>2</sup> , 87.49 to 87.53%, and 28.75 to 28.85%, respectively, for the  $\text{SnS}_2$  ETL. For the  $\text{WS}_2$ ETL,  $J_{\rm sc}$  slightly improved from 34.55 to 34.554 mA cm<sup>-2</sup>, while the FF and PCE decreased from 79.23 to 79.05% and 24.56 to 24.49%, respectively. Similarly, *J<sub>sc</sub>*, FF, and PCE changed from 30.22143 to 30.34129 mA  $cm^{-2}$ , 84.46 to 84.32%, and 21.1 to 21.15%, respectively, for the  $In_2S_3$  ETL. However, for both the  $WS_2$  and  $In_2S_3$  ETLs, the value of  $V_{oc}$ remained constant. Such independence of the ETL thickness over a wide range exposes the versatility of the practical film fabrication for application to the proposed device structures. Moreover, considering the sufficient spectral transparency of the ETL and practical thin-film fabrication challenges, we chose an optimum thickness of 10 nm for further study.

**3.5. Optimization Donor Density and Bulk Defect Density of the SnS<sub>2</sub> ETL.** [Figure](#page-5-0) 6a depicts the effect of variation in the doping concentration  $(N_D)$  of the SnS<sub>2</sub> ETL on the PV parameters in the range of  $1 \times 10^{10}$  to  $1 \times 10^{20}$ cm<sup>-3</sup>. The  $\bar{V}_{\text{oc}}$  remained almost the same up to  $N_{\text{D}} = 1 \times 10^{17}$ cm<sup>−</sup><sup>3</sup> , and it started to decrease (from 0.979 to 0.9786) when  $N_{\rm D}$  increased over  $1 \times 10^{17}$  cm<sup>-3</sup>, while the *J*<sub>sc</sub> and FF

<span id="page-5-0"></span>

Figure 5. Thickness effects of various ETLs.

remained constant at 34.58 mA cm<sup>−</sup><sup>2</sup> and 87.91%, respectively. A similar trend was observed for the three structures corresponding to changes in  $N_D$ .<sup>[5050](#page-12-0)</sup> Thus, the optimum value of  $N_D$  of the ETL was chosen to be  $10^{17}$  cm<sup>-3</sup> considering the realistic behavior of  $SnS<sub>2</sub>$  thin films for the next stages of this study.

Figure 6b shows how the  $N_t$  (bulk defect density) of the  $SnS<sub>2</sub> ETL$  impacts the effectiveness of the proposed structure. The *V*<sub>oc</sub>, *J<sub>sc</sub>*, FF, and consequently, the PCE remained nearly constant up to  $N_t = 10^{18}$  cm<sup>-3</sup>, while the  $N_t$  of SnS<sub>2</sub> increased from  $10^{12}$  to  $10^{20}$  cm<sup>-3</sup>, showing notable vulnerability gain defects. Thereafter, the FF started to decrease from 87.91 to 87.24%, resulting in a reduction in the PCE from 29.74 to 29.48% for increasing  $N_t$  from  $10^{18}$  to  $10^{20}$  cm<sup>-3</sup>. This behavior of PV parameters was found to be consistent with a previous report.<sup>[51](#page-12-0)</sup> Thus, the  $N_t$  of 10<sup>17</sup> cm<sup>-3</sup> was chosen as an ideal value for further study in later sections.

**3.6. Influence of Layer Thickness and Defect Density Variation of the RbPbBr3 Absorber on PV Performance.** [Figure](#page-6-0) 7 shows the change in the defect density and thickness of the RbPbBr<sub>3</sub> absorber layer from  $10^{10}$  to  $10^{18}$  cm<sup>-3</sup> and from 0.1 to 2.0 *μ*m, respectively, to examine the effect of defect density on solar cell performance. The solar cell performance metrics degrade dramatically when the  $RbPbBr<sub>3</sub>$  defect density exceeds  $10^{12}$  cm<sup>-3,[51](#page-12-0)</sup> The ETA, FF, *J<sub>sc</sub>* and  $V_{\text{oc}}$  of the Al/  $FTO/SnS_2/RbPbBr_3/Au$  structures decrease from 30.33 to 9.44%, 87.91 to 61.66%, 35.2 to 20.17 mA  $\text{cm}^{-2}$ , and 0.98 to 0.7592 V, respectively, when the bulk defect density and absorber layer thickness are altered from  $10^{10}$  to  $10^{18}$  cm<sup>-3</sup> and 0.1 to 2.0  $\mu$ m. According to [Figure](#page-6-0) 7a, the highest  $V_{\text{oc}}$  of 0.98 V is achieved when the thickness is above  $1 \mu m$ , and the defect density is below  $1 \times 10^{12}$  cm<sup>-3</sup>. However, when the defect density exceeds  $10^{12}$  cm<sup>-3</sup>,  $V_{\text{oc}}$  significantly drops to 0.7592 V. According to [Figure](#page-6-0) 7b, the thickness must be greater than 1  $\mu$ m, and the defect density must be lower than 10<sup>12</sup> cm<sup>-3</sup> in

Figure 6. Impact of variation of (a) donor density and (b) bulk defect density of the  $SnS<sub>2</sub> ETL$ .

<span id="page-6-0"></span>

Figure 7. Effects of absorber thickness and defect density variations on photovoltaic performance parameters: (a)  $V_{oo}$  (b)  $J_{so}$  (c) FF, and (d) ETA.

order to reach the highest *J*<sub>sc</sub> value of 35.2 mA cm<sup>−2</sup>. Figure 7c shows that the FF reaches its maximum value of 87.91% when the thickness is greater than or equal to 1 *μ*m, and the defect density is less than or equal to  $10^{12}$  cm<sup>-3</sup>. However, if the defect density increases beyond  $10^{12}$  cm<sup>-3</sup>, the FF sharply drops to 61.66%.

Figure 7d demonstrates that the thickness range of 0.25−2.0  $\mu$ m and the defect density of up to 10<sup>12</sup> cm<sup>-3</sup> have resulted in the greatest conversion efficiency, exceeding 29%. The introduction of high defect states in the absorber layer results in a high carrier recombination rate in the cell, which in turn leads to a reduction in cell performance.<sup>59−[61](#page-12-0)</sup> The best combination of parameters for achieving the highest possible PCE of 29.75% has been identified, which includes a constant thickness of 1.0  $\mu$ m for the RbPbBr<sub>3</sub> absorber layer and a defect concentration of  $10^{12}$  cm<sup>-3</sup>. At these values, the solar cell achieved a *V*oc of 0.9789 V, a *J*sc of 35.57863 mA/cm<sup>2</sup> , and an FF of 87.91%.

**3.7. Influence of Layer Thickness and Interface Defect Density Variation of the RbPbBr<sub>3</sub> Absorber on PV Performance.** The characteristics that control how light and electricity interact with one another can be changed by defects in the material system. The effectiveness of the cell is

also significantly impacted by the quality of the interface. To investigate the impact of interface defect density on the performance of the  $RbPbBr<sub>3</sub>$ -based solar cell, [Figure](#page-7-0) 8 shows the changes in the defect density of the  $SnS_2/RbPbBr_3$ interfaces from  $10^{10}$  to  $10^{18}$  cm<sup>-2</sup> and in the thickness of the RbPbBr<sub>3</sub> absorber layer from 0.1 to 2.0 μm, respectively. When the interface defect density of  $SnS_2/RbPbBr_3$  exceeds  $10^{10}$ cm<sup>−</sup><sup>2</sup> , respectively, there is a notable decrease in the solar cell performance parameters. When the defect densities of the SnS<sub>2</sub>/RbPbBr<sub>3</sub> interfaces are increased from  $10^{10}$  to  $10^{18}$  cm<sup>-2</sup> and the absorber layer thickness is increased from 0.1 to 2.0  $\mu$ m, the values of ETA, FF,  $J_{\rm sc}$  and  $V_{\rm oc}$  decrease.

The following values decrease, in particular: ETA (30.29− 4.92%), FF (87.9−61.48%), *J*sc (35.08993 to 35.20497 mA cm<sup>−</sup><sup>2</sup> ), and *V*oc (0.979 to 0.2282 V). The *V*oc values are shown in [Figure](#page-7-0) 8a. [Figure](#page-7-0) 8b demonstrates that the maximum value of *J<sub>sc</sub>*, which is 35.20497 mA cm<sup>-2</sup>, is attained at a thickness of 2.0  $\mu$ m and a defect density below 1 × 10<sup>14</sup> cm<sup>-2</sup>. When the thickness of the absorber is 1.0  $\mu$ m, the interface defect density is less than or equal to  $10^{14}$  cm<sup>-2</sup>. [Figure](#page-7-0) 8c illustrates that the FF achieves its highest value of 87.9%. However, FF considerably decreases to 61.48% when the interface defect density reaches  $10^{14}$  cm<sup>-2,</sup> and the absorber thickness is less

<span id="page-7-0"></span>

Figure 8. Effects of absorber layer thickness and interface defect density (RbPbBr<sub>3</sub>/SnS<sub>2</sub>) variations on photovoltaic performance parameters: (a) *V*<sub>oc</sub> (b) *J*<sub>sc</sub> (c) FF, and (d) ETA.

than or equal to 1.0 *μ*m. According to Figure 8d, a maximum conversion efficiency of over 29.75% is attained when the thickness is between 0.1 and 2.0  $\mu$ m, and the defect density is below  $10^{16}$  cm<sup>-2</sup>.

**3.8. Analysis of Carrier Generation and Recombination.** [Figure](#page-8-0) 9a,b displays the carrier generation and recombination rates for the position in the optimized  $SnS_2/$ RbPbBr<sub>3</sub> heterostructure device, respectively. In the carrier generation process, electrons excited by incident photons in the VB jump to the CB, leaving a hole in the VB and producing electron−hole pairs. This carrier generation increases by the release of holes and electrons produced by these PSCs, which retain avalanche behaviors. For the modified structure, the highest generation rate was seen at a location of around 1 *μ*m. The higher photon absorption at that particular position resulted in the highest rate of generation in that region (absorber layer). Herein, an almost linear total generation was obtained in the optimized  $SnS_2/RbPbBr_3$  heterostructure with the highest value of over  $10^{22}$   $\text{cm}^3 \text{s}^{-1}$ , while the highest total recombination value was observed at almost  $10^{16}$   $\rm cm^2$   $\rm s^{-1}$ simultaneously in similar regions. SCAPS-1D determines the

generation of the pairs of electron−hole, *G*(*x*), corresponding to the net flashing photon flux,  $N_{phot}(\lambda, x)$ , using eq 2 as follows

$$
G(\lambda, x) = \alpha(\lambda, x) \cdot N_{\text{phot}}(\lambda, x)
$$
 (2)

However, holes and electrons of the CB fall in the recombination process after generation, having a shorter lifetime than their lifetime, owing to the presence of recombination centers (defects), higher carrier density, and longer diffusion length. This is because, in comparison to other regions, the greater number of electrons inside the CB cross the energy barrier and are shipped toward the VB, where they stabilize and occupy the exact location of a hole that exists. The energy levels generated by such events cause a noticeable effect on the recombination of the electron−hole profile. Additionally, the distribution rates of recombination may not be uniform due to grain boundaries and defects. Thus, defects and their distribution, carrier density, and duration of charge carriers have an impact on the rate of recombination in PSCs, which requires careful consideration during practical device fabrication with minimal recombination centers.

<span id="page-8-0"></span>

**Figure 9.** (a) Total generation, (b) total recombination, (c) hole concentration, and (d) electron concentration rate with respect to distance of the optimized device.

Figure 9c,d shows the hole and concentration rates for the positions in the optimized  $SnS_2/RbPbBr_3$  heterostructure device. The effective density of states (DOS) in the valence bands and the hole concentration are caused by acceptor concentrations in the absorbers that are liable for net carrier mobility, which is undoubtedly beneficial for high-efficiency device fabrication.<sup>62,63</sup> A stable hole concentration of  $10^{17}$ cm<sup>−</sup><sup>3</sup> throughout the absorber regions with a low electron concentration of 10<sup>12</sup> cm<sup>−</sup><sup>3</sup> was obtained at optimized conditions under the chosen parameters demonstrated in previous tables. The hole mobility of RbPbBr<sub>3</sub> perovskite with less e-h recombination and a significant carrier generation rate was found to be an effective and promising absorber material for the fabrication of high-performance thin-film solar cells combined with a  $SnS<sub>2</sub> ETL$ .

**3.9. Effect of Temperature on the Proposed Optimized RbPbBr3-Based Perovskite.** [Figure](#page-9-0) 10 demonstrates the impact of the working temperature (WT) of the  $RbPbBr_3$ perovskite on various PV parameters changing from 275 to 400 K. In the proposed  $\text{SnS}_2$  ETL-based optimized device,  $V_{\text{oc}}$  FF, and consequently, the PCE decreased from 1.014 to 0.8337 V, 88.98 to 83.21%, and 31.2 to 23.99%, respectively, while *J*sc increased from 34.574 to 34.586 mA  $cm^{-2}$  corresponding to the change of WT from 275 to 400 K. An increase in the working temperature causes an acceleration of carrier velocity in random directions, which results in unwanted collisions as well as deformation stress; therefore, the carrier recombination domination occurs, resulting in a marked reduction of the cell performance.<sup>[64](#page-12-0)</sup>

In contrast, as the temperature increases, the series resistance  $(R_s)$  increases, and the diffusion length reduces severely; therefore, the cell performance decreases mark-edly.<sup>[62](#page-12-0),[65](#page-12-0)</sup> Though high performance occurs at 275 K, we consider 300 K to be an optimized value. Besides, this value is approximately close to the room temperature (298 K). Thus, the working temperature of  $\leq 300$  K was found to be a favorable range for obtaining high performance from the proposed device with the  $SnS<sub>2</sub> ETL$ .

**3.10. Analysis of** *J*−*V* **and QE Properties of RbPbBr3- Based Optimized Structures.** [Figure](#page-9-0) 11a exhibits the *J*−*V* (current density−voltage) graphs of the circuit at the absorber layer thickness in the range of 250−2000 nm with an

<span id="page-9-0"></span>

Figure 10. Effect of the working temperature of the  $RbPbBr<sub>3</sub>$ -based optimized structure.

optimized  $N_A$  of 10<sup>17</sup> cm<sup>-3</sup>,  $N_t$  of 10<sup>12</sup> cm<sup>-2</sup>, and  $N_{int}$  of 10<sup>16</sup> cm<sup>-2</sup> of the proposed PSC. The optimum absorber thickness was found to be 1000 nm with a systematical analysis. The PCE was found to be 29.75% with  $V_{\text{oc}}$  of 0.979 V,  $J_{\text{sc}}$  of 34.58 mA  $\text{cm}^{-2}$ , and FF of 87.91% for  $\text{SnS}_2$ , while the PCE was 21.15 and 24.57% for  $In_2S_3$  and WS<sub>2</sub> ETLs, respectively.

QE refers to a ratio of the photogenerated charge carriers to photons impacting the cell,<sup>[66](#page-12-0)–[68](#page-12-0)</sup> as shown in Figure 11b, for an absorber thickness range of 250−3000 nm. The QE reached almost saturation over the 1000 nm thickness of the absorber layer in the quantum efficiency (QE) curve of the corresponding devices. It sharply decreased from the highest value (∼99%) to zero, i.e., at the cutoff position of ∼950 nm (∼1.3 eV). Considering the trade-off among PV parameter values, the optimized thickness was chosen as 1000 nm. These QE spectra support the obtained *J*−*V* characteristics.<sup>[69](#page-12-0)</sup>

### **4. CONCLUSIONS**

We designed and optimized inorganic RbPbBr<sub>3</sub>-based perovskite solar cells for three different S-chalcogenide ETLs of  $SnS_2$ ,  $WS_2$ , and  $In_2S_3$  with a heterostructure of Al/FTO/ETL/ RbPbBr3/Au for the first time. The band gap alignment of  $RbPbBr<sub>3</sub>$  was found to match well with  $SnS<sub>2</sub>$  as an efficient electron transport compared to  $WS_2$  and  $In_2S_3$  ETLs after a systematic simulation. To obtain an optimized device performance and understand the charge transport characteristics, including electron−hole generation and recombination, several major influencing parameters, such as the thickness of the layer, bulk defect density, doping concentration, interfaces defect density, and working temperature, were investigated. Further, a study on the optimized device with the most potential ETL  $(SnS_2)$  layer was performed to explore the carrier generation and recombination behavior. Finally, a comparative study among PV parameters of the proposed optimized device and those reported in the literature was performed to explore the benchmark of efficient RbPbBr<sub>3</sub>based photovoltaics. The highest PCE was 29.75% for the  $\mathrm{SnS}_2$ ETL with  $V_{\text{oc}}$  of 0.979 V,  $J_{\text{sc}}$  of 34.58 mA cm<sup>-2</sup>, and FF of 87.91%, while PCEs of 21.15 and 24.57% were obtained for the  $In_2S_3$  and  $WS_2$  ETLs, respectively. Additionally, the QE results validate the obtained outcomes. Thus, the  $SnS<sub>2</sub> ETL$  shows strong potential for use in future high-efficiency Rb-based PSC devices.
