Background: Several nomograms have been proposed to facilitate the determination of initial gentamicin dosing regimens in clinical settings. This study aimed to assess the predictive performance of these nomograms in Korean patients.

Methods: Gentamicin concentrations were determined in 84 patients with infective endocarditis (IE) and in 95 patients with other infections. All patients underwent therapeutic drug monitoring in Seoul National University Hospital from 2006 to 2012. Individual pharmacokinetic parameters were estimated using a Bayesian method, which predicted steady state peak and trough serum concentrations. Six nomograms were evaluated in patients with “other” infections: the Thomson guidelines, Hull-Sarubbi table, and Rule of Eights, for multiple daily dosing; and the Hartford nomogram, Barnes-Jewish Hospital nomogram, and Sanford Guide, for extended-interval dosing. In IE patients, synergistic combination dosing nomograms, based on the American Heart Association dosing interval guidelines, were evaluated.

Results: Gentamicin dosing nomograms performed poorly in attaining the target peak serum concentrations. Multiple-daily dosing nomograms predicted peak serum gentamicin concentrations better than did the extended-interval dosing nomograms (31.9%–72.3% vs 4.3%–45.7%, respectively). Similarly, in patients with IE, the once-daily dosing nomogram resulted in a significantly lower percentage of patients achieving target peak gentamicin concentrations than that associated with the thrice-daily dosing nomogram ($P=0.0015$). All of the multiple-daily dosing, extended-interval dosing, and synergistic combination dosing nomograms predicted the nontoxic target trough concentrations in >80% of patients.

Conclusion: Gentamicin dosing nomograms performed poorly in achieving the target peak serum concentrations. New gentamicin nomograms may be required in patients with IE, particularly for once-daily dosing. Therapeutic drug monitoring is highly recommended for gentamicin to ensure that the target concentrations are achieved.

Keywords: antibiotics, infectious endocarditis, therapeutic drug monitoring, Bayesian method

Introduction

Gentamicin is an aminoglycoside antibiotic with bactericidal activity against aerobic gram-negative organisms. Although gentamicin has been widely used, it is potentially toxic to the kidney (nephrotoxicity) and the inner ear (ototoxicity).¹ Therefore, it is essential to use an appropriate initial dose and dosing interval for gentamicin to minimize its toxicity, while maintaining its efficacy. When determining the appropriate gentamicin dose, many factors need to be considered, eg, infection site, patient age, sex, body weight, serum creatinine, and creatinine clearance.^{2–4}

Several nomograms and dosing guidelines have been developed to optimize the initial dosage regimen for gentamicin. These can be categorized into three groups:

multiple-daily dosing (MDD), extended-interval dosing (EID), and gram-positive synergistic combination dosing (SCD). MDD regimens administer gentamicin intermittently, twice- or thrice-daily. Although MDD has been conventionally used, once-daily administration of gentamicin in EID regimens may be preferable because of the increased convenience. In fact, several studies in various clinical settings demonstrated that EID was as safe as or safer than MDD, with equal efficacy.^{5–8} SCD is generally reserved for patients with serious infections, such as infective endocarditis (IE), in which β -lactams or vancomycin is frequently coadministered.^{9,10}

One study in Kuwait revealed that up to 63% of patients were outside the target ranges when an initial gentamicin dose regimen was chosen based on six MDD nomograms.¹¹ Similarly, another study in the USA reported that EID nomograms, including the Hartford nomogram, did not achieve the target peak concentration of 20 $\mu\text{g/mL}$ in most patients.¹² To the best of our knowledge, no study has ever reported the predictive performance of SCD nomograms. Moreover, although the MDD, EID, and SCD nomograms mentioned above have been widely used for the determination of gentamicin dose in Korea, their performances have not yet been systematically reviewed.

Based on this understanding, the objective of the present study was to evaluate the predictive performance of several gentamicin nomograms and dosing guidelines, in Korean patients. To this end, various gentamicin nomograms were retrospectively evaluated, by comparing the percentage of patients whose predicted peak and trough concentrations achieved the target therapeutic and nontoxic ranges, respectively.

Materials and methods

Subjects

Gentamicin concentrations were determined in patients >19 years of age, who underwent therapeutic drug monitoring (TDM) at Seoul National University Hospital

from January 2006 to December 2012. Subjects with one or more sets of paired steady state peak and trough serum gentamicin concentrations, with documented actual sample collection times, were included. Subjects with incomplete demographic data relating to age, serum creatinine, or body weight were excluded. Subjects were also excluded if they were on dialysis or pregnant. Eligible subjects were classified into two infection groups; IE, and infections other than IE (OI). The study protocol was reviewed and approved by the Institutional Review Board at Seoul National University Hospital (approval number 1309-016-518). This study was conducted in compliance with the ethical principles set forth in the Declaration of Helsinki (sixth revised), Good Clinical Practices,¹³ and other regulatory laws and requirements.

Determination of gentamicin concentrations

Serum gentamicin concentrations were determined by chemiluminescent immunoassay using the Architect i2000SR (Abbott Laboratories, Abbott Park, IL, USA).¹⁴ The precision for the gentamicin assay was 3.6%–8.2%. The lower limit of quantitation was 0.2 $\mu\text{g/mL}$.

Dosing nomograms

Table 1 shows the MDD and EID nomograms evaluated in OI patients and the SCD nomograms evaluated in IE patients. The following three MDD nomograms were evaluated: the Thomson guidelines, Hull-Sarubbi table, and the Rule of Eights. The Thomson guidelines (Table S1) recommend a dose ranging from 80 to 160 mg, with a dosing interval of 8 hours, 12 hours, or 24 hours, depending on the patient's creatinine clearance and body weight.¹⁵ In the Hull-Sarubbi table, a loading dose is administered, followed by a maintenance dose, at a dosing interval determined by the patient's creatinine clearance and body weight;¹⁶ the dosing chart shown in Table S2 was used to determine a maintenance dose for each patient in the present study. Lastly, the Rule of

Table 1 Target serum concentrations of gentamicin by nomogram

Classification	Nomogram	Dosing interval (h)	Peak ($\mu\text{g/mL}$)	Trough ($\mu\text{g/mL}$)	Target infections	References
Multiple-daily dosing (MDD)	Thomson guidelines, Hull-Sarubbi table, Rule of Eights	8, 12	5–10	<2	Infections other than infective endocarditis	11,15,28
Extended-interval dosing (EID)	Hartford nomogram, Barnes-Jewish Hospital nomogram, Sandford Guide	24, 36, 48	>20	<2	Infections other than infective endocarditis	19,29,30
Synergistic combination dosing (SCD)	American Heart Association guideline	8, 12 24	3–4 >10	<1 <1	Infective endocarditis	20,31,32

Eights assigns doses of 1.0 to 1.66 mg/kg to be administered at variable intervals, depending on the patient's serum creatinine.¹⁷ In this study, a median dose of 1.33 mg per patient's ideal body weight was chosen. The dosing interval in the Rule of Eights is 8 hours for patients with normal serum creatinine (ie, <1.24 mg/dL); for those with elevated serum creatinine, dosing is repeated every 8 hours, 12 hours, or 24 hours, selecting whichever is closest to eight times the patient's serum creatinine level (mg/dL).¹⁷ The typical target peak and trough concentrations for MDD are 5–10 µg/mL and <2 µg/mL, respectively.¹⁴

For EID, the Hartford nomogram, the Barnes-Jewish Hospital nomogram, and the Sanford Guide were evaluated. The Hartford nomogram¹⁵ and the Barnes-Jewish Hospital nomogram¹⁸ recommend gentamicin at 7.0 mg/kg and 5.0 mg/kg, respectively, with dosing intervals of 24 hours, 36 hours, or 48 hours, depending on the patient's creatinine clearance (Table S3). Similarly, the Sanford Guide recommends a dose ranging from 4.0 to 5.1 mg/kg, with a dosing interval of 24 hours or 48 hours, based on the patient's creatinine clearance (Table S4).¹⁹ The target peak concentration for EID is >20 µg/mL, higher than that of MDD, while its target trough concentration is the same, <2 µg/mL.

Gentamicin remains an important therapy, in both the European and American guidelines, for SCD treatment of patients with IE. For example, the American Heart Association guideline recommended a dose of 3 mg/kg/day, based on the patient's actual body weight.²⁰ Although MDD has been widely used for the treatment of IE, recent reports have indicated that once-daily regimens can also be employed.¹⁷ In the present study, we chose clinically practical dosing intervals of 8 hours, 12 hours, or 24 hours for the evaluation of SCD nomograms.²⁰ Because other antibiotics are concomitantly used with gentamicin in SCD, its target peak and trough concentrations are typically lower than those of MDD and EID, at 3–4 µg/mL (peak) and <1 µg/mL (trough) for 8-hour dosing, and >10 µg/mL and <1 µg/mL for 24 hours dosing, respectively. The present study evaluated nomograms for initial dosing only. Additional details of the nomograms and guidelines are provided in Tables S1–S4.

Calculation of individual pharmacokinetic (PK) parameters and steady state peak and trough concentrations

The Abbottbase® Pharmacokinetic System program (version 1.10; Abbott Laboratories) was used to derive individual PK parameters and steady state peak and trough concentrations throughout the study.¹⁸ The Pharmacokinetic

System program is based on the Bayesian maximum a posteriori method, using a one-compartment linear model.¹⁸ Like other Bayesian dose individualization methods, the prior model estimates the population PK parameters of gentamicin as follows:

$$V_d \text{ (L)} = 0.27 \times \text{WT (kg)}, \text{ CV} = 30\%, \quad (1)$$

$$\text{CL}_{\text{TB}} \text{ (L/h)} = \text{CL}_{\text{R}} + \text{CL}_{\text{NR}}, \quad (2)$$

$$\text{CL}_{\text{R}} \text{ (L/h)} = 0.815 \times \text{CL}_{\text{cr}}, \text{ CV} = 40\%, \text{ and} \quad (3)$$

$$\text{CL}_{\text{NR}} \text{ (L/h)} = 0.0025 \times \text{LBW (kg)}, \text{ CV} = 25\%, \quad (4)$$

where V_d represents the volume of distribution; CL_{TB} is total body clearance; CL_{R} and CL_{NR} are renal and nonrenal clearance, respectively; CL_{cr} is creatinine clearance, calculated using the Cockcroft–Gault equation; WT is actual body weight; LBW is lean body weight,¹⁹ calculated for females, as

$$\text{LBW} = (\text{height} - 150 \text{ cm}) \times 0.9 + 45 \text{ kg}, \quad (5)$$

or for males, as

$$\text{LBW} = (\text{height} - 150 \text{ cm}) \times 0.9 + 50 \text{ kg}; \quad (6)$$

and CV is the interindividual coefficient of variation. Based on equations 1–4, individual PK parameters were estimated, taking into account gentamicin concentrations and covariates for each patient.

After individual PK parameters had been estimated, steady state peak and trough concentrations were predicted using the dose-estimator section of the PKS program as follows:

$$C_{\text{ss}} = \frac{K_0}{k_e \times V_d} \times \frac{(1 - e^{-k_e \cdot t_{\text{inf}}})}{(1 - e^{-k_e \cdot \tau})} \times e^{-k_e \cdot t}, \quad (7)$$

where C_{ss} represents predicted steady state concentration, t_{inf} is the duration of intravenous infusion (30 minutes), K_0 is the dosing rate, t is the time of concentration measurement after termination of drug infusion, k_e is the elimination rate constant, and the τ is the dosing interval. The steady state peak and trough gentamicin concentrations were the values predicted using equation 7, at the end of intravenous infusion and immediately before the next scheduled administration, respectively.

Statistical analysis

SAS software (version 9.3; SAS Institute Inc., Cary, NC, USA) was used for statistical analysis in the present study.

Demographic data and individual PK parameters were summarized using descriptive statistics, such as mean and standard deviation. All of the continuous data were first evaluated for normality of distribution by plotting a histogram followed by the Shapiro–Wilk test for normality. The mean values were compared between infection groups (OI vs IE), using the Student's *t*-test or the Mann–Whitney *U* test for normally or nonnormally distributed variables, respectively. The predicted peak and trough concentrations were assessed against the target therapeutic and nontoxic ranges for gentamicin, respectively. Predictive performance was then defined as the percentage of subjects whose peak and trough concentrations achieved the target therapeutic and nontoxic goals, respectively. Using the GLLIMIX procedure in SAS, generalized linear mixed models were developed to compare the predictive performance of MDD and EID nomograms in OI patients, and SCD nomograms in IE patients. Furthermore, pair-wise post hoc comparisons were made based on the models, with multiplicity adjusted. A two-sided $P \leq 0.05$ was considered to be statistically significant.

Results

Subjects

Of 703 patients who underwent gentamicin TDM, 524 patients were excluded because: their peak or trough gentamicin concentrations were not available or were obtained at nonsteady state ($n=352$); they were <19 years old ($n=64$); demographic data were missing ($n=65$); or they were on dialysis or pregnant ($n=43$) (Figure 1). As a result, the final analysis population included a total of 179 patients, who were classified into two infection groups: IE ($n=84$) and OI ($n=95$). Of these 179 patients, 110 were male and 69 were female. Baseline characteristics, including individual PK parameters, were comparable between the OI and IE patient groups, except that patients with OI were significantly older than those with IE (49 vs 56 years) ($P=0.0005$) (Table 2).

Predictive performance of nomograms

In the OI group, MDD nomograms generally resulted in a higher percentage of patients achieving the target therapeutic peak concentrations than did EID nomograms (31.9%–72.3% vs 4.3%–45.7%) (Table 3); fewer patients attained the therapeutic target using the Rule of Eight compared with the Hartford nomogram. On the other hand, nontoxic target trough concentrations were reached in a relatively large proportion of patients ($>80\%$) by all of the MDD and EID nomograms, although more patients achieved the nontoxic target using EID nomograms than using MDD nomograms

(94.7%–97.9% vs 83.0%–90.4%) (Table 3). Collectively, when assessed against both the peak and trough targets, the Thomson guidelines performed significantly better than did the other nomograms, while the predictive performances of the Barnes-Jewish Hospital nomogram and the Sanford Guide were lowest, at 6.4% and 4.3%, respectively (Figure 2).

Similar performance findings were noted for the SCD nomograms in patients with IE. For example, the once-daily dosing nomogram resulted in a significantly lower percentage of patients achieving the target therapeutic peak concentrations than did the thrice-daily dosing nomogram (21.2% vs 38.8%) ($P=0.0146$) (Table 4). A high percentage of patients attained the target nontoxic trough concentration (80.0%–100.0%) (Table 4), and no significant difference was observed between the nomograms in this respect. Together, these data indicated that thrice-daily dosing was associated with the best predictive performance in SCD nomograms, for both peak and trough concentration targets (Figure 2).

Discussion

This study indicated that gentamicin dosing nomograms performed poorly in attaining the intended target peak (therapeutic) concentrations, irrespective of the dosing frequency and the type of infection. For example, the percentage of patients who failed to attain the target peak concentrations was $>50\%$ for most nomograms, which even increased to $>95\%$ for some EID nomograms, such as the Barnes-Jewish Hospital nomogram and the Sanford Guide. However, the target trough concentrations were achieved relatively well by all of the nomograms (80%–100%) (Tables 3 and 4). Furthermore, the percentage of patients whose predicted peak and trough concentrations achieved both the therapeutic and the nontoxic targets, respectively, was $<50\%$ for all of the nomograms, with the exception of the Thomson guidelines, which performed slightly better (67.0%) (Figure 2).

The poor predictive performance of these gentamicin dosing nomograms, particularly in achieving the target peak concentrations, may reflect large interindividual variability in the PK parameters for gentamicin, leading to different tissue accumulation and dispositional characteristics between subjects.^{21,22} Furthermore, the typical population gentamicin PK parameters can vary depending on the clinical setting. For example, they may be altered in seriously ill patients receiving a great deal of hydration.^{5,6,23,24} Because the use of nomograms oversimplifies these differences, poor predictive performance may result, as clearly exemplified in this study. Moreover, given that the peak gentamicin concentrations are likely to be overestimated due to the longer distributional half-life,²² the predictive

Table 2 Baseline characteristics of the subjects (n=179)

Characteristics ^a	Patients with infective endocarditis (n=85)	Patients with infections other than infective endocarditis (n=94)	Total patients (n=179)
Age (yr)	49±17	56±15	53±17
Sex (male/female)	48/37	62/32	110/69
Body weight (kg)	59.0±11.0	62.0±11.0	60.7±11.0
Height (cm)	165.4±9.0	165.4±8.4	165.4±8.7
Serum creatinine (mg/dL)	1.0±0.4	1.0±0.5	1.0±0.4
Creatinine clearance ^b (mL/min)	80.9±31.0	79.6±31.5	80.1±29.5
Individual pharmacokinetic parameters for gentamicin			
Total clearance (L/h)	4.2±1.7	4.3±1.6	4.2±1.7
Total volume of distribution (L)	19.6±5.1	17.7±4.1	18.6±4.7
Elimination rate constant (h ⁻¹)	0.2±0.1	0.3±0.1	0.2±0.1
Half-life (h)	4.0±2.9	3.4±1.9	3.7±2.4

Notes: All data are presented as mean ± standard deviation, except for sex. ^aNo significant difference was found between patients with infective endocarditis and those with other infections, except for age ($P=0.012$); ^bestimated by the Cockcroft–Gault equation.

Table 3 Predictive performance of multiple-daily dosing and extended-interval dosing nomograms in patients with infections other than infective endocarditis (n=94)

Classification	Nomogram	C_{peak}^a ($\mu\text{g/mL}$)	C_{trough}^a ($\mu\text{g/mL}$)	Patients achieving the target concentration range ^b	
				Peak ^c n (%)	Trough n (%)
Multiple-daily dosing	Thomson guidelines	7.9 \pm 2.3	1.0 \pm 1.5	68 (72.3%)	85 (90.4%)
	Hull-Sarubbi table	5.5 \pm 1.3	1.1 \pm 0.9	55 (58.5%)	85 (90.4%)
	Rule of Eights	5.0 \pm 1.7	1.3 \pm 1.4	30 (31.9%)	78 (83.0%) ^d
Extended-interval dosing	Hartford nomogram	20.4 \pm 4.8	0.4 \pm 0.9	43 (45.7%)	89 (94.7%)
	Barnes-Jewish Hospital nomogram	14.5 \pm 3.6	0.3 \pm 0.7	6 (6.4%)	86 (95.7%)
	The Sanford Guide	13.1 \pm 3.8	0.4 \pm 0.8	4 (4.3%)	86 (97.9%) ^e

Notes: ^aMean \pm standard deviation is presented; ^bthe target ranges of peak (therapeutic) and trough (nontoxic) gentamicin concentrations were 5–10 $\mu\text{g/mL}$ and $<2 \mu\text{g/mL}$, respectively, for multiple daily dosing; and $>20 \mu\text{g/mL}$ and $<2 \mu\text{g/mL}$, respectively, for extended-interval dosing; ^call pair-wise comparisons, based on a generalized linear mixed model, were statistically significant, except for the Hull-Sarubbi table vs the Hartford nomogram; and the Barnes-Jewish Hospital nomogram vs the Sanford Guide; ^dsignificantly lower vs all the extended-interval dosing nomograms; ^esignificantly higher vs all the multiple daily dosing nomograms.

performance in achieving the therapeutic target can further deteriorate. Therefore, the present study confirmed that TDM is still essential in patients treated with gentamicin.

It is worth noting that the predictive performance of the once-daily dosing nomograms was generally poorer than that of the MDD nomograms with respect to attaining target therapeutic peak concentrations. For example, the percentage of patients who achieved the target peak concentration was only 4.3%–6.4% for the Barnes-Jewish Hospital nomogram

and the Sanford Guide, two of the EID nomograms (Table 3). Likewise, only one-fifth of IE patients achieved the target peak concentration using once-daily dosing, whereas this proportion was increased to almost two-fifths by thrice-daily dosing (Table 4).

In a recent study conducted in patients with IE, once-daily gentamicin dosing was as efficient as twice-daily dosing and did not associate with increased nephrotoxicity.²¹ In contrast, the SCD nomograms using once-daily dosing in the present study resulted in only 14.1% of IE patients achieving both the target peak and the target trough concentrations – far fewer than the 36.5% who achieved this using thrice-daily dosing (Figure 2). Because no SCD nomogram takes into account renal function, which plays an important role in gentamicin clearance,²⁵ a new nomogram may be needed in patients with IE, particularly for once-daily dosing regimens.

We used the Abbottbase PKS system to estimate individual PK parameters. It employed the Bayesian method, which has performed better than other approaches, such as the traditional two-point Sawchuk–Zaske method.²⁵ The better performance of the Bayesian method is possible because it incorporates, not only population-derived PK parameters based on patient demographic data, but also, the dosing history and observed peak and trough serum concentrations to determine individual dosage requirements.^{26,27}

The present study had several limitations. Because of its retrospective nature, the predicted performance of nomograms was not assessed against clinical outcomes, such as treatment success, disappearance of target infections, or development of toxicity. Moreover, a one-compartment model was used in the present study (because blood samples were sparsely collected at trough and peak), although gentamicin may behave

**Figure 2** Percentage of patients achieving the target peak and trough gentamicin concentrations.

Notes: The nomograms investigated were: the Thomson guidelines; Hull-Sarubbi table; the Rule of Eights; the Hartford nomogram; Barnes-Jewish Hospital nomogram; the Sanford Guide; and the American Heart Association guideline. Pair-wise comparisons were made among multiple-daily dosing and extended-interval dosing nomograms combined, and synergistic combination dosing nomograms, respectively. All pair-wise comparisons (based on a generalized linear mixed model) were statistically significant, except for those marked as not significant.

Abbreviations: AHA, American Heart Association guideline; NS, not significant; q8h, every 8 hours; q12h, every 12 hours; q24h, every 24 hours.

Table 4 Predictive performance of synergistic combination dosing nomograms in patients with infective endocarditis (n=85)

Classification	Nomogram	C_{peak}^a	C_{trough}^a	Patients achieving the target concentration range ^b	
				Peak n (%)	Trough ^d n (%)
Synergistic combination dosing	Thrice-daily dosing	3.7±1.7	0.9±1.2	33 (38.8%) ^c	68 (80.0%)
	Twice-daily dosing	4.8±1.8	0.4±0.2	22 (25.9%)	85 (100.0%)
	Once-daily dosing	7.4±2.8	0.4±0.3	18 (21.2%)	76 (89.4%)

Notes: ^aMean ± standard deviation is presented; ^bthe therapeutic target ranges of peak and trough gentamicin concentrations were 3–4 µg/mL and <1 µg/mL, respectively, for multiple daily dosing (thrice- and twice-daily); and >10 µg/mL and <1 µg/mL, respectively, for once-daily dosing; ^csignificantly higher vs the once-daily dosing nomogram ($P=0.0146$, a generalized linear mixed model); ^dnot significant between any pair of nomograms ($P=0.8845$, a generalized linear mixed model).

following a two-compartment model.²⁷ Another limitation was that subjects were relatively young, with normal or moderately-altered renal function, which cautions against the generalization of the study results to elderly subjects or to patients with chronic kidney disease. Therefore, future prospective studies employing more frequent PK samplings and various clinical settings are warranted to address all of these limitations.

Conclusion

Most gentamicin dosing nomograms failed to achieve the target peak concentrations, although the Thomson guidelines performed slightly better than the other methods. New nomograms are needed in IE patients because the current AHA guideline did not predict the therapeutic peak concentration effectively, particularly for once-daily dosing. TDM of gentamicin is highly recommended.

Supplementary material

Table S1 Thomson guidelines

CL _{cr} ^a (mL/min)	Weight (kg)				
	40–49	50–59	60–69	70–79	>80
20–29	80 (24)	100 (24)	100 (24)	120 (24)	120 (24)
30–39	100 (24)	100 (24)	120 (24)	120 (24)	140 (24)
40–49	80 (12)	100 (12)	140 (24)	140 (24)	160 (24)
50–59	100 (12)	100 (12)	120 (12)	120 (12)	160 (24)
60–69	100 (12)	120 (12)	140 (12)	140 (12)	140 (12)
70–79	120 (12)	140 (12)	140 (12)	140 (12)	160 (12)
80–89	140 (8)	140 (12)	140 (12)	160 (12)	160 (12)
90–99	140 (8)	140 (8)	160 (8)	160 (8)	180 (12)
>100	140 (8)	160 (8)	160 (8)	160 (8)	180 (12)

Notes: The table shows dose (mg) and dosing interval (8, 12, or 24 h) determined from the patient's weight and creatinine clearance (CL_{cr}). ^aEstimated by the Cockcroft–Gault equation.

Table S2 Hull-Sarubbi table

CL _{cr} ^a (mL/min)	Percentage of LD ^b to use for MD	Dosing interval (h)
>90	84	8
80	80	8
70	76	8
60	84	12
50	79	12
40	72	12
30	86	24
20	75	24–36
<20	Give LD ×1, then check random level(s)	

Notes: ^aEstimated by the Cockcroft–Gault equation; ^bloading dose (LD) (=2 mg/kg of dosing weight) is first determined, and maintenance dose (MD) and dosing interval is consequently selected based on patient's creatinine clearance (CL_{cr}).

Table S3 Hartford and Barnes-Jewish Hospital nomograms.

Nomogram	Gentamicin dose (mg/kg)	Dosing interval (h)		
		CL _{cr} ^a ≥60 mL/min	CL _{cr} ^a 40–59 mL/min	CL _{cr} ^a ≥20–39 mL/min
Hartford nomogram	7	24	36	48
Barnes-Jewish Hospital nomogram	5	24	36	48

Note: ^aEstimated by the Cockcroft–Gault equation.

Abbreviation: CL_{cr}, creatinine clearance.

Table S4 The Sanford Guide nomogram

CL _{cr} (mL/min) ^a	Dosing regimen	
	Dose (mg/kg)	Dosing interval (h)
≥80	5.1	24
60–79	4.0	24
40–59	3.5	24
30–39	2.5	24
20–29	4.0	48

Note: ^aEstimated by the Cockcroft–Gault equation.

Abbreviation: CL_{cr}, creatinine clearance.

Drug Design, Development and Therapy

Dovepress

Publish your work in this journal

Drug Design, Development and Therapy is an international, peer-reviewed open-access journal that spans the spectrum of drug design and development through to clinical applications. Clinical outcomes, patient safety, and programs for the development and effective, safe, and sustained use of medicines are a feature of the journal, which

has also been accepted for indexing on PubMed Central. The manuscript management system is completely online and includes a very quick and fair peer-review system, which is all easy to use. Visit <http://www.dovepress.com/testimonials.php> to read real quotes from published authors.
