Tailored treatment to MRD response: A phase I/II study for newly diagnosed multiple myeloma patients using high dose twice-weekly carfilzomib (45 and 56 mg/m²) in combination with lenalidomide and dexamethasone

To the Editor:

Newly diagnosed multiple myeloma (NDMM) patients who achieve and sustain minimal residual disease (MRD) negative complete response/stringent complete response (CR/sCR) demonstrate clinical benefit with prolonged progression-free survival and overall survival.¹ In this phase I/II clinical trial, we investigated twice weekly high doses of carfilzomib (45 and 56 mg/m²) in combination with lenalidomide and dexamethasone. We also explored the prevailing doctrine of fixed number of cycles of induction therapy by integrating MRD testing into the clinic to guide the total number of cycles delivered during induction therapy. To our knowledge, this is the first trial reporting results that fully incorporate MRD testing into a clinical decision-making algorithm for NDMM.

We conducted a single center phase I/II clinical trial investigating high doses of twice-weekly carfilzomib in combination with lenalidomide and dexamethasone NDMM patients. The study (NCT 02937571) was approved by Memorial Sloan Kettering Institutional Review Board. Phase I consisted of a standard 3 + 3 schema design based on dose-limiting toxicities occurring in cycle one. Phase II used a Simon's optimal two-stage design at the MTD dose to determine proportion of patients achieving CR/sCR MRD negativity within 12 cycles (CR/sCR MRD-negative unpromising rate 20% and promising rate 45%). Treatment consisted of 28-day cycles with carfilzomib 20/45 mg/m² or 20/56 mg/m² on days 1, 2, 8, 9 15 and 16; lenalidomide 25 mg on days 1-21' and dexamethasone 40 mg weekly (cycles 1-4) then 20 mg weekly (after cycle four). Patients achieving CR/sCR (defined by IMWG 2016 criteria) underwent MRD testing. Patients achieving MRD-negative status received two additional cycles from conversion time and ceased further protocol therapy. while patients with less than an MRD-negative response continued therapy until treatment completion (max 12 cycles), disease progression, or unacceptable toxicity. Patients deemed eligible for autologous hematopoietic cell transplantation (AHCT) underwent stem cell collection after six cycles, and then continued with therapy. Decision about AHCT and maintenance was deferred until after completion of protocol therapy. Multiparametric flow cytometry MRD assessments were performed on the first pull of each aspirate in a single 10-color tube with a limit of detection of at least 6×10^{-6} (ie, three cells in 1 million) with at least 3 million cell acquisitions.²

Between October 2016 and June 2018, 29 patients with NDMM gave consent and enrolled in the study. Data cutoff was May 14, 2020. Baseline on the 29 patients in demographics are outlined (online Appendix S1, Figures S1–S3, Tables S1 and S2). Nine patients were treated in the phase I portion of the trial (3 - KRd-45 and 6 - KRd-56). In the phase I portion, no DLTs occurred and the MTD of 56 mg/m² of twice-weekly carfilzomib was further investigated. An additional 20 patients [eight patients stage one + 11 patients stage two + one patient withdrew consent] were enrolled and treated with KRd-56 in phase II. One patient withdrew consent after one cycle of therapy was evaluable for toxicity, and 28 patients were evaluable for

toxicity and response. The median follow-up for the study was 36.7 months (95% CI: 27.6–39.8 months). In phase 1, no DLTs occurred in KRd-45 or KRd-56 dose level cohorts within first cycle. The most common grade 3/4 hematologic treatment related adverse events (TRAE) was lymphopenia 7(24%) and the most common grade 3/4 non-hematologic TRAE was electrolyte abnormalities 10 (34%) (Figure 1A). Thirteen serious adverse events occurred: seven (24%) infections, one (3%) atrial fibrillation, one (3%) non-ST elevation myocardial infarction (NSTEMI), one (3%) thromboembolic, one (3%) decreased ejection fraction, one (3%) gastrointestinal perforation, and one (3%) severe constipation. All grade cardiac TRAE was 17% with serious grade 3/4 at the following: atrial fibrillation two (6%), NSTEMI myocardial infarction one (3%), and decreased ejection fraction one (3%).

Best responses at MTD dose level KRd-56 were CR/sCR MRDnegative 12/25 (48%: 95% CI: 0.28-0.69). CR/sCR MRD unconfirmed 1/25 (4%; 95% CI: 0-0.2), VGPR 10/25 (40%; 95% CI: 0.21-0.61), PR 2/25 (8%; 95% CI: 0.01-0.26), ORR 25/25 (100%; 95% CI: 0.86-1.0), and \geq VGPR serum response with MRD-negative bone marrow 15/25 (60%; 95% CI: 0.39-0.79) (Figure 1B). The median number of cycles for patients to achieve CR/sCR MRD-negative status were eight (range, 2-12), and median number of cycles delivered to the CR/sCR MRD-negative group were 10 (range, 2-12). Median PFS for both KRd-56 and combined cohorts were not reached while 36-month PFS rates were 73% (95% CI: 55%-96%) for KRd-56 and 77% (95% CI: 60%-97%) for combined. Median OS was not reached for KRd-56 cohort or combined cohorts. Additionally, with high-risk disease being defined as R-ISS III or unfavorable cytogenetics. 36-month PFS was 84% (95% CI: 66%-100%) standard-risk vs 50% (95% CI: 22%-100%) high-risk in KRD-56 cohort (P = .07) and 87% (95% CI: 72%-100%) standard-risk vs 50% (95% CI: 22%-100%) high-risk in combined cohorts (P = .03). In comparing outcomes between CR/sCR MRD-negative patients and all others, 24-month PFS in a one-year landmark analysis was 89% (95% CI: 0.71-1) vs 64% (95% CI: 0.38-1) for KRd-56 cohort (P = .3). For individual dosing cohorts and both combined dosing cohorts, the median duration of MRD-negative response sustained in the bone marrow was not reached. At the post-induction 12-month MRD time point, 11/13 (85%) CR/sCR MRD-negative patients remain MRD-negative sustained or clinically sustained in a CR/sCR serological response, while 2/13 (15%) CR/sCR MRD-negative patients converted to MRD positivity before meeting criteria for progressive disease (PD) (Figure 1C). Among three patients that were VGPR MRD-negative at end of induction, two patients seroconverted to CR/sCR and remain MRD-negative at the 12-month follow-up mark (patient two and five), while one patient turned MRD-positive at 12-month time-point before having PD (patient 13). For the six patients who were MRD-positive at the conclusion of induction therapy, two remain MRD-positive at the 12-month MRD time-point, two patients seroconverted to CR/sCR from VGPR (MRD uncertain), and two patients sustained their MRDpositive response at the 12-month MRD time-point before PD.

In this phase I/II study, we found KRd-56 to be tolerable and effective in NDMM patients. The overall toxicity profile of KRd-45 and KRd-56 was comparable to KRd-36 regimens³ with an all-grade cardiac TRAE of 17% and grade 3/4 of 3%-6%, similar to previously

described all-grade at 18.1% and grade 3/4 at 8.2%.⁴ The KRd-56 regimen yielded a CR/sCR MRD-negative rate of 48% and a ≥VGPR MRD-negative rate of 60%, meeting primary endpoint and similar to KRd-36 regimens with and without AHCT.^{3,5} As an exploratory approach, our study took an alternative strategy to the existing framework of a fixed number of cycles followed by upfront AHCT by delivering personalized tailored number of cycles based on MRD response and delaying the timing of AHCT. The MRD status directed induction is supported by the observation in the IFM 2009 study that NDMM patients achieving MRD-negative disease status (10⁻⁶) receiving RVd combination therapy followed by maintenance irrespective of upfront or delayed AHCT showed no difference in OS⁶. Ongoing studies, such as the FORTE trial (NCT02203643), are currently investigating outcomes between four cycles of KRD-AHCT-4 cycles of KRD and12 KRD cycles, but treatment assignments in this study are independent of MRD responses. We found that the median number of cycles delivered to patients achieving CR/sCR MRD-negative status was eight cycles (range, 2-12), higher than the usual four cycle limit threshold followed by immediate AHCT and notably ranging in a wide number of cycles needed to achieve MRD negativity. This highlights the individualized nature of disease response. Our study capped maximum number of cycles at 12. While it is unclear if additional therapy would have further deepened response rates, we found that three patients converted from VGPR to CR/sCR during maintenance. Accordingly, most patients went onto maintenance therapy and inferior PFS was not observed. The PFS outcomes were similar between MRDnegative and MRD-positive response groups, possibly due to short follow-up or lack of consistency in post-trial therapies. For high-risk disease, 36-month PFS favored standard-risk disease patients. Admittedly, it is unclear whether obtaining a simple MRD-negative response after induction therapy is an optimal strategy for decision making in the high-risk disease setting due to rapidly evolving kinetics. Perhaps MRD surveillance is particularly relevant in high-risk disease patients and these patients should be considered for intensification regardless of MRD status. Although numbers are limited, this is highlighted in our study by five out of seven high-risk cytogenetic patients achieving CR/sCR MRD negativity during induction but durability only lasted in two patients (one-AHCT and one-ixazomib-lenalidomide therapy post-induction) and the other two high-risk disease CR/sCR MRDnegative patients clinically progressed after lenalidomide maintenance (one dropped out). Despite these observations, an MRD responseadapted approach demonstrated 36-month PFS rates at 73% (95% CI: 55%-96%) for KRd-56 and 77% (95% CI: 60%-97%) for combined dosing cohorts, similar to published studies of 50%-80% PFS at 36 months.^{3,5} At current follow-up, median PFS was not reached using an MRD response adapted approach, and approximately 85% remained CR/sCR and/or MRD-negative sustained at the post-12 month MRD follow-up time-point. By way of this unique proofin-concept trial design, we demonstrated the safety and efficacy of KRd-56 as an induction regimen for NDMM, yielding high rates of MRD negativity while examining the role of MRD testing into clinical management. Future work needs to be done to validate MRD response adapted approaches and sustainability in clinical practice.
