Purpose: We investigated the relationship between metabolic syndrome (MetS) and its components and erythrocyte parameters such as red blood cell count (RBC) and hemoglobin (Hb) levels, and their association with the risk of deep myometrial invasion in endometrioid endometrial carcinoma (EEC).

Patients and Methods: A total of 473 women diagnosed with EEC between January 2012 and December 2018 were included in the study. MetS was diagnosed using a modified version of the Chinese Diabetes Society 2004 criteria. Demographic and clinical characteristics were stratified by MetS and compared. Logistic regression analyses were performed to calculate the odds ratios (ORs) of myometrial invasion.

Results: The prevalence of MetS was 18.8% (89/473). RBC and Hb levels were significantly higher in EEC patients with MetS. RBC and Hb values increased linearly with the number of MetS components. The OR of the MetS risk increased across the RBC quartiles (OR=2.212, 95% confidence interval [CI]=1.125-4.350, P<0.05). Among EEC patients with MetS, the OR of deep myometrial invasion increased with the decrease of the RBC quartiles (P=0.037). Similarly, in EEC patients with obesity and hyperglycemia or with ≥2 MetS criteria, the lowest RBC level (Q1) was a risk factor for deep myometrial invasion compared with the reference RBC group (Q4, P<0.05). However, this trend was not evident in EEC patients without MetS and its components.

Conclusion: EEC with MetS and its components had higher RBC and Hb levels. The association between the erythrocyte parameters and myometrial invasion differed with MetS. RBC was identified as a risk factor of myometrial invasion in EEC patients with MetS and its components.

Keywords: metabolic syndrome, endometrioid endometrial carcinoma, red blood cell count, hemoglobin, myometrial invasion

Introduction

Endometrioid endometrial carcinoma (EEC) is a common gynecological tumor, and its prevalence is increasing over the past few decades. The increased incidence of EEC could be related to a greater overall prevalence of obesity and metabolic diseases (obesity, hyperglycemia, and hyperlipidemia), in addition to the aging of the population.[1] Prognostic factors for EEC have been investigated detailly, and the most important are the surgical FIGO (International Federation of Gynecology and Obstetrics) stage, depth of myometrial invasion, histologic tumor grade, and lymph node status.[1] Therefore, it is very important to identify the subgroups of EEC

patients with a higher risk of poor outcomes to provide accurate and appropriate individualized treatment and lifestyle guidance for adaptation.

Metabolic syndrome (MetS) is a complex disorder defined by a cluster of coexistent metabolic abnormalities characterized by insulin resistance including obesity, hypertension, hyperglycemia, and dyslipidemia.[2] The prevalence of MetS is high in EEC patients, while the prognosis of EEC patients with MetS is poor.[3]

Inflammation is the core stage of tumorigenesis and development.[4] The molecules associated with MetS do not only directly act on tumor cells but also promote the development and progression of endometrial cancer by further remodeling the tumor immune microenvironment.[5] Anemia of inflammation due to prolonged immune activation is common in cancer patients.[6] Although chronic inflammation may inhibit erythropoiesis,[7,8] several studies have reported that MetS patients with a low degree of inflammation are often accompanied by increased erythropoiesis. These findings are relevant because, increased erythropoiesis may give these people a false impression of overall "good" health.

Therefore, the aim of this study was to explore the associations and clinical consequences of erythrocyte parameters such as red blood cell count (RBC) and hemoglobin (Hb), and MetS on the risk of deep myometrial invasion in EEC.

Patients and Methods
Study Patients
This descriptive study is a retrospective study involving the medical records of patients diagnosed with EEC. From January 2012 to December 2018, 526 patients with EEC treated in the Fujian Maternal and Child Health Hospital were enrolled. Of these, 473 met the eligibility criteria, i.e., they had stage I–IV disease treated with hysterectomy and bilateral salpingoophorectomy, with or without pelvic and para-aortic lymph node dissection. Patients were staged based on the FIGO guidelines. The EEC histological subtype was diagnosed pathologically after operation. Patients with non-endometrioid histological subtypes or incomplete medical records were excluded. Sixteen patients with other concomitant cancers (3 ovarian, 4 breast, 3 rectal, and 6 other cancers) were excluded due to the possible confounding neoplastic effect on hematopoiesis. None of the patients had a past history of endometrial cancer or had received neoadjuvant chemotherapy or radiotherapy before operation. Finally, 473 patients were included for further analysis. The study was approved by the Ethics Committee of Fujian Maternity and Child Health Hospital, Affiliated Hospital of Fujian Medical University (No. 2020–2002) and was conducted according to the principles of the Declaration of Helsinki. As this retrospective study did not harm the rights and health of patients and protected their privacy and personal information, the ethics committee waived the requirement to obtain informed consent.

Data Collection and Measurements
Data were obtained from patients' files available through our institution's biochemical database. The anthropometric parameters, biochemistry, and hematological counts routinely collected before surgery during hospitalization were obtained. Ergonomic parameters were measured by trained personnel in accordance with standardized protocols. Height, weight, systolic blood pressure (SBP), and diastolic blood pressure (DBP) were measured multiple times and their averages calculated. Body mass index (BMI) was calculated by dividing the weight (kg) by the height (m^2). The venous blood samples used in the analysis were taken before surgery. The median time from blood analysis to surgical treatment in our patient cohort was 2 (range 0 to 7) days.

Definition of Metabolic Syndrome
According to the criteria set forth by the Chinese Diabetes Society (CDS) in 2004,[9] a person was diagnosed with MetS when she had at least three of the following criteria: (I) obesity: BMI $\geq$ 25 kg/m^2, (II) hyperglycemia: fasting blood glucose $\geq$ 6.1 mmol/L or 2-hour plasma glucose $\geq$ 7.8 mmol/L or previously diagnosed diabetes, (III) dyslipidemia: triglycerides $\geq$ 1.7 mmol/L or high-density lipoprotein cholesterol (HDL) < 1.0 mmol/L in women, (IV) hypertension: systolic/diastolic blood pressure $\geq$ 140/90 mmHg or currently receiving antihypertensive therapy.

Quartiles of Erythrocyte Parameter Levels
Erythrocyte parameter levels were categorized into quartiles on the basis of individual distributions (RBC: Q1 < 4.00×10^12/L, Q2 = 4.00–4.27×10^12/L, Q3 = 4.28–4.59×10^12/L, Q4 > 4.59×10^12/L; Hb: Q1 < 114 g/L, Q2 = 115–125 g/L, Q3 = 126–133 g/L, Q4 >134 g/L).

Statistical Analysis

Quantitative data were analyzed using the Student's test or Mann–Whitney *U*-test, while qualitative variables were analyzed using the Chi-squared test. Continuous data and RBC and Hb levels were expressed as mean ± standard deviation (SD). A one-way ANOVA and χ^2 test were conducted to test the composition of MetS in the subjects according to the RBC count and hemoglobin quartile. Logistic regression analyses were performed to calculate the adjusted odds ratios (ORs) of the erythrocyte parameters associated with myometrial invasion by MetS and its components. All statistical analyses were performed using the Statistical Package for the Social Sciences (SPSS) V.22.0 (SPSS, Chicago, Illinois, USA). A P value < 0.05 was considered statistically significant.

Result

Patient Characteristics

In total, 89 (18.8%) of the 473 EEC patients were diagnosed with MetS. The average age of the MetS group was significantly higher than that of the non-MetS group (P = 0.001). MetS components were significantly more prevalent in all the MetS standard groups than in the non-MetS groups (P < 0.001). Both RBC and Hb levels were

Notes: *P < 0.05; **P < 0.01.
Abbreviations: MetS, metabolic syndrome; Criteria I MetS, body mass index (BMI) ≥ 25 kg/m^2; Criteria II MetS, fasting blood glucose ≥ 6.1 mmol/L or 2-hour plasma glucose ≥ 7.8 mmol/L or previously diagnosed diabetes; Criteria III MetS, triglycerides ≥ 1.7 mmol/L or high-density lipoprotein cholesterol (HDL) < 1.0 mmol/L in women; Criteria IV MetS, systolic/diastolic blood pressure ≥ 140/90 mmHg or currently receiving antihypertensive therapy.

significantly higher in the MetS group than in the non-MetS group (P = 0.008; P = 0.024). Among prognostic factors including FIGO stage, myometrial infiltration, lymphatic infiltration, and histological grade, the difference was only statistically significant in myometrial infiltration (P < 0.001, Table 1). We followed up 473 patients, with a median follow-up time of 45.5 months, the Kaplan-Meier analysis of OS are shown in Supplementary Figure 1.

Relationship Between MetS and Erythrocyte Parameter Levels

Circulating Hb and RBC levels were analyzed in the whole cohort of patients according to the 4 individual diagnostic criteria of MetS (obesity, hyperglycemia, dyslipidemia, hypertension; Table 2). RBC levels were significantly higher in patients with all the 4 MetS criteria than those who did not (P < 0.05). Hb levels were higher in patients with hyperglycemia and hypertension (P < 0.05, Table 2).

Figure 1 shows that the characteristics of the 473 subjects classified into the various RBC and Hb quartiles. The prevalence of MetS increased in a dose-dependent manner with an increase in RBC and Hb levels. However, the difference was not statistically significant (P = 0.119, P = 0.078). We compared the prevalence of abnormal MetS parameters in the RBC and Hb quartiles. The prevalence of obesity and dyslipidemia was significantly higher with an increase in RBC (P = 0.014, P = 0.012). There was no

statistically significant difference in the prevalence of dyslipidemia and hypertension in the different RBC quartiles (P = 0.073, P = 0.307). The prevalence of hyperglycemia and hypertension was significantly different among different Hb quartiles (P = 0.030, P = 0.001), while there was no statistically significant difference in the prevalence of obesity and hyperglycemia (P = 0.402, P = 0.057).

We also calculated the mean RBC and Hb concentration by the MetS components. RBC levels increased linearly with an increase in the number of MetS components from 0 to 4 (P = 0.002). Especially, the mean concentration of RBC significantly increased above the two parameters of the MetS components (P < 0.05). There was a significant increasing trend in the Hb levels with the presence of ≤3 MetS components (P = 0.042; Figure 2).

Adjusted ORs of MetS and its components associated with RBC or Hb quartiles are listed in Table 3. As the concentration of RBC or Hb increased, the lowest quartile was considered as the reference group. After adjusting for age, the OR of MetS risk increased across the RBC quartiles (OR = 2.212, 95% confidence interval [Cl] = 1.125–4.350; P < 0.05). With reference to the lowest RBC quartile (Q1), the OR was 2.322 for the highest RBC quartile (Q4) in the obese patients and 2.288 for RBC (Q4) in the patients with hyperglycemia. Compared with Hb (Q1), the OR for being hypertensive increased across the Hb quartiles, even when adjusted by age (OR = 2.028, 95% Cl = 1.123–3.663; P < 0.05).

Effect of RBC and MetS Components on Deep Myometrial Invasion of EEC

We also analyzed the influence of: (a) the MetS status, (b) the number of MetS criteria met, (c) each individual criterion of MetS, and (d) circulating RBC and Hb levels on deep myometrial invasion of EEC (Table 4). A significant association was observed between the risk of deep myometrial invasion in our cohort of patients and menopause. Remarkably, after adjusting

for age, menopausal status, each individual criterion of MetS and tumor markers, obesity was significantly associated with a higher risk of deep myometrial invasion (OR = 2.101, 95% Cl = 1.128-3.916, P = 0.019). Furthermore, our results showed that the risk of deep myometrial invasion increased with a decrease in the RBC quartiles (P = 0.037), and the risk of deep muscle infiltration increased by 2.806-fold (95% Cl = 1.311–6.005, P = 0.008) in patients with the lowest RBC quartile (Q1) compared with those in the reference group (Q4). However, we did not find any association between Hb and the risk of deep myometrial invasion. Multivariate logistic regression analysis indicated that menopausal status, obesity, RBC, and CA125 were the independent risk factors correlated with deep myometrial invasion.

Further exploratory analyses were carried out to evaluate the association of RBC with deep myometrial invasion in different MetS states. After adjusting for age, the lowest RBC quartile (Q1) had a 3.842-fold increased risk of deep myometrial invasion in EEC patients with MetS compared with those in the reference group (Q4). Similarly, in patients with two or more MetS criteria or with obesity and hyperglycemia, the lowest RBC quartile (Q1) was a risk factor for deep myometrial invasion compared with the reference group (Q4) (OR = 3.836, P = 0.004, 95% CI = 1.533–9.596; OR = 2.961, P = 0.022, 95% CI = 1.170–7.497; OR = 4.109, P = 0.015, 95% CI = 1.323–11.759). However, no association was observed between low RBC levels and deep myometrial invasion in patients without MetS or ≤ two MetS criteria or with obesity and hyperglycemia (P > 0.05, Figure 3). Risk of deep myometrial invasion in EEC patients with MetS, low RBC to others are shown in Supplementary Figure 2.

Discussion

In this cross-sectional study, we found higher RBC and Hb levels in EEC patients with MetS. Preoperative MetS especially obesity or hyperglycemia are risk factors for deep myometrial invasion of EEC. Low RBC levels increased the risk of deep myometrial invasion in EEC patients with MetS and its components.

Over the past decades, the prevalence of MetS has increased dramatically worldwide.[10] According to the criteria set forth by the Chinese Diabetes Society in 2004 in the China Health and Nutrition Survey in 2009, the prevalence of MetS among female participants aged 18 years and above was 8.7%, and the prevalence of MetS correlated positively with age.[10] The prevalence of MetS was 16.2–17.0% according to the data assessed by the CDS criteria for other cancer patients in Fujian Province,

China.[11,12] The prevalence of MetS among the older patients in our study was relatively high, at 18.8%.

Increased erythropoiesis in EEC patients with MetS has been found in a number of previous studies in different populations.[13,14] Increased erythrocyte parameters may be a new aspect of the insulin resistance syndrome. In this EEC population, we also found that RBC and Hb, especially RBC, were positively correlated with the presence of MetS components and the number of MetS components. The association of erythrocytes with MetS and its components can be explained by the fact that EEC patients often present with complications such as hyperinsulinemia and insulin resistance. Studies have shown that human insulin can directly act on erythrocyte progenitor cells and promote erythropoiesis.[15] In vitro studies have also shown that insulin and insulin-like growth factor I can promote the proliferation and differentiation of human bone marrow and circulating erythroid progenitors into erythrocytes.[16] The increase of erythropoiesis may be a new MetS parameter for EEC patients.

Myometrial invasion is a well-known predictor of recurrence of endometrial cancer and is important in the decision-making of adjuvant therapy.[1,17] Previous studies have found that MetS is closely related to the stage, grade, vascular invasion, and lymph node metastasis of endometrial carcinoma, and is an independent prognostic factor of EEC.[3] However, the correlation between metabolic abnormalities and myometrial infiltration is not clear. Diabetes mellitus is associated with poor recurrence-free survival (RFS) and overall survival in type I endometrial cancer.[18] Obesity is associated with high morbidity and mortality of endometrial cancer.[19] Obesity can affect the RFS of women with a high risk of endometrial cancer.[20,21] After adjusting for BMI, the association between various lipid levels and the tumor risk was generally reduced, suggesting that a large part of the association between abnormal lipid metabolism and tumors is mediated by obesity. Our findings also showed a positive correlation between obesity, abnormal blood glucose, and myometrial invasion, which means that MetS is associated with features of an aggressive tumor biology.

An interesting aspect of this study is the relationship between anemia-related erythrocyte parameters and myometrial invasion of EEC in patients with MetS. Anemia and several types of cancer originating in different organs are associated with advanced disease and poor prognosis, including the breast and ovaries.[22,23] For endometrial cancer, previous studies have shown that low Hb is associated with advanced EEC and low survival rates.[24,25] Other studies have shown the association between decreased Hb before treatment and poor histopathological features, but it is not regarded as an independent factor for poor survival in multivariate analysis.[26] However, there are few studies on RBC levels and the prognosis of EEC. Our study showed that the anemia-related erythrocyte parameter RBC rather than Hb was associated with myometrial invasion of EEC. In EEC patients with MetS, the decrease in RBC is associated with deep myometrial invasion especially in those with obesity and hyperglycemia.

The reason for this pattern is not obvious. Cancer-related anemia leads to a decrease in RBC and Hb and is caused by multiple factors. These could be nutritional deficiency, iron metabolism disorder, chronic systemic inflammation, and tumor bone marrow infiltration.[27] Since EEC is most often diagnosed without distant metastases, the observed reduction of RBC and Hb may be caused by something other than direct bone marrow infiltration. It is convincing to attribute anemia to concurrent uterine bleeding, which is a potential confounding factor. Anemia is also considered to be a paraneoplastic syndrome, a phenomenon of cancer biological invasion.

Tumor cells produce and secrete several soluble cytokines (such as interleukin-1, interferon-γ, and tumor necrosis factor) that may reduce the levels of RBC and Hb by hemolysis, inhibition of erythropoietin production, and damage of the erythropoietin response of erythroid bone marrow precursors.[28] In addition, cancer produces cytokines that cause systemic inflammation, thereby reducing the production of red blood cells and shortening their survival time. MetS is also associated with chronic subclinical inflammation caused by high levels of pro-inflammatory mediators, and secondary inflammation may coordinate the occurrence and development of cancer through local and systemic processes.[5] Therefore, we propose that in EEC patients with dysregulation of glycolipid metabolism, the remodeling of the tumor immune microenvironment may make the decreased RBC more closely related to tumorigenesis and development.

This study had some limitations. Without access to data on the drug treatment of MetS, it was impossible to adjust the effect of MetS treatment in the patients with EEC. This may have led to systematic bias, confounding of the association of MetS and its components with erythrocyte parameters and its possible causal relationship with poor prognosis. In addition, there were no other basic hematological parameters in our population-based study design to characterize the type of anemia, nor did it take into account the control of inflammatory conditions that may have a potential impact on hematopoietic organs to minimize potential bias.

Conclusion

In conclusion, our results show that the prevalence of MetS in patients with EEC is high, and MetS is often accompanied by increased RBC and Hb, while decreased RBC rather than Hb is a risk factor for deep myometrial invasion in EEC patients, especially those with MetS. Given the high prevalence of MetS in EEC, clinicians may be able to identify individuals at high risk for prognosis early on by closely monitoring metabolic abnormalities and giving guidance for a healthy lifestyle. In addition, it is recommended that RBC be included in the prognostic assessment of EEC patients, especially those with metabolic abnormalities since RBC may be a new marker of poor prognosis in EEC patients with metabolic disorders.
