Abstract

Background: Early prediction of tumor response to neoadjuvant chemotherapy (NACT) is crucial for optimal treatment and improved outcome in breast cancer patients. The purpose of this study is to investigate the role of shear wave elastography (SWE) for early assessment of response to NACT in patients with invasive breast cancer.

Methods: In a prospective study, 62 patients with biopsy-proven invasive breast cancer were enrolled. Three SWE studies were conducted on each patient: before, at mid-course, and after NACT but before surgery. A new parameter, mass characteristic frequency (f_{mass}), along with SWE measurements and mass size was obtained from each SWE study visit. The clinical biomarkers were acquired from the pre-NACT core-needle biopsy. The efficacy of different models, generated with the leave-one-out cross-validation, in predicting response to NACT was shown by the area under the receiver operating characteristic curve and the corresponding sensitivity and specificity.

Results: A significant difference was found for SWE parameters measured before, at mid-course, and after NACT between the responders and non-responders. The combination of $E_{\text{mean}2}$ and mass size (s_2) gave an AUC of 0.75 (0.95 CI 0.62–0.88). For the ER+ tumors, the combination of $E_{\text{mean_ratio}1}$, s_1 , and Ki-67 index gave an improved AUC of 0.84 (0.95 CI 0.65–0.96). For responders, f_{mass} was significantly higher during the third visit.

Conclusions: Our study findings highlight the value of SWE estimation in the mid-course of NACT for the early prediction of treatment response. For ER+ tumors, the addition of Ki-67 improves the predictive power of SWE. Moreover, f_{mass} is presented as a new marker in predicting the endpoint of NACT in responders.

Introduction

Neoadjuvant chemotherapy (NACT) is an established therapeutic strategy for operable breast cancers and locally advanced breast cancers and allows more patients to undergo breast-preserving surgery [1, 2]. A pathological complete response (pCR) to NACT is associated with increased disease-free interval. However, responses to NACT are quite variable. With the increased use of NACT, it is crucial to have an accurate prediction of tumor response to NACT.

Current techniques available for monitoring response to NACT are positron emission tomography (PET) [3], sonography, mammography, magnetic resonance imaging (MRI) [4–7], and shear wave elastography (SWE) [8, 9]. Conventional sonography and mammography have poor reliability in evaluating the size of residual tumor after chemotherapy [10]. SWE is a recently developed low-cost imaging technique for measuring tissue stiffness in a noninvasive and quantitative manner with high reproducibility [11–15].

Tissue stiffness has been demonstrated to be significantly correlated with tumor growth as cancer development and progression require extensive reorganization of the extracellular matrix (ECM) [16]. Increased deposition of collagen and other ECM molecules enhances the stiffness of tumoral stroma [17–19]. Changes in tumor stiffness were significantly greater in patients who had a good response to NACT compared to those resistant to NACT [20]. Breast cancer pre- and post-treatment stiffness obtained from SWE was significantly correlated with the presence of residual cancer [8, 9]. A study in [21] showed that the SWE stiffness measured after 3 cycles of NACT and changes in stiffness from baseline were strongly associated with pCR after 6 cycles. The combination of the post-treatment SWE and greyscale ultrasound has also been shown to be promising for end-of-treatment identification of residual disease and thus response to NACT, with similar accuracies found in assessment by MRI [22].

In the current study, a new SWE parameter mass characteristic frequency (f_{mass}) was used. f_{mass} is defined as the ratio of the averaged minimum shear wave speed (SWS) within the regions of interest (ROIs) to the largest mass dimension. The physical meaning of the new parameter can be explained as the inverse of the maximum shear wave propagation time in a breast mass. The motivation for using f_{mass} is that in SWE, the SWS of small masses is often underestimated due to their small size compared to the wavelength. This error may lead to the false-negative diagnosis of such masses. f_{mass} represents the SWS weighted by the inverse of mass diameter; therefore, f_{mass} assumes a larger value for masses that are too small. Thus, one may expect f_{mass} to be a more robust parameter in SWE than SWS itself. However, we

want to emphasize that f_{mass} is not meant to compensate for the underestimation error of SWS in a mathematical sense. Our intention is to introduce f_{mass} as a new metric that improves the characterization of breast masses in a statistical sense. The purpose of this study was to investigate the role of SWE parameters, including mass characteristic frequency, in evaluating the breast tumor response to the NACT treatment. For ER-positive tumors, the combination of the SWE parameters with Ki-67 was further studied to improve the sensitivity and specificity of the response prediction.

Methods

Study population

This prospective study was Health Insurance Portability and Accountability Act (HIPAA) compliant and was approved by the Institutional Review Board (IRB) (IRB application #12-003329). From January 2014 to September 2020, 62 female patients (age range 27–78 years) with 62 biopsy-proven invasive breast cancers were recruited in this study. During the recruitment, patients with prior mastectomy or breast implant were excluded. One patient with a previous lumpectomy in the contralateral breast was included in this study. A signed written informed consent with permission for publication was obtained from each enrolled patient prior to the study.

Imaging

SWE studies were conducted for each patient at three time points: before initiation of NACT, at the mid-course of NACT, and after completion of NACT but prior to surgery. A flow diagram of the study population is summarized in Fig. 1.

The 2D SWE scanning was performed by one of our two experienced sonographers, using the GE LOGIQ-E9 ultrasound clinical scanner equipped with a 2–8 MHz linear array probe (9L-D, GE Healthcare, Wauwatosa, WI) for both the conventional B-mode and SWE data acquisition. To reduce motion artifacts, patients were instructed to suspend respiration for approximately 3 s during the data acquisition. The SWE measurement was acquired within a rectangle-shaped field of view, which covered the whole lesion and the adjacent normal tissue. For each lesion, along the same orientation, at least four SWE images were obtained. One of the consistent stiffness maps was chosen to draw ROIs. Three non-overlapping ROIs, 3 mm in diameter, were placed at the stiffest position of the lesion, with peritumoral stroma included. One ROI was placed at the surrounding normal tissue. The mean SWS, maximum SWS, minimum SWS, and standard deviation of the SWS inside each ROI were calculated by the ultrasound machine. The SWS for the tumor was represented by the average values of the three ROIs placed at the stiffest position. A

new shear wave parameter, mass characteristic frequency, represented by f_{mass} , is used in this paper: $f_{mass} = 1000V_{min}/d$, where f_{mass} is with unit Hz, V_{min} is the minimum SWS with unit m/s, and d is the mass size in mm and recorded as the maximum dimension of the tumor shown on the B-mode image. Figure 2 illustrates the measurements for calculating f_{mass} .

Clinical pathologic data

The parameters for residual cancer burden (RCB) measurement for each patient were obtained from the

surgical pathology report, and the RCB score was calculated with an empirical equation: $RCB = 1.4(f_{inv}d_{prim})^{0.17} + [4(1-0.75^{LN})d_{met}]^{0.17}$ [23]. RCB was on a continuous scale and was further categorized as 0 (RCB = 0), I ($0 < RCB < =1.36$), II ($1.36 < RCB < =3.28$), or III (RCB > 3.28). Categories 0 and I were regarded as responders while categories II and III were regarded as non-responders [23, 24]. Of the 62 patients included in this study, 60 underwent lumpectomy or mastectomy, and the corresponding RCB scores were calculated from the surgical reports. Two patients did not undergo surgery, one progressed on neoadjuvant chemotherapy and died before undergoing surgery, and one developed metastatic disease, and therefore, surgery was not indicated and ultimately died 3.5 years after diagnosis. The two deceased patients were categorized as non-responders. The MRI dimensions (AP, trans, and SI) were read from the clinical MRI image that was acquired close to the date of the SWE scanning. The MRI volume was calculated as the product of the three dimensions (volume = AP × trans × SI). The clinical MRI was based on the dynamic enhanced protocol using intravenous (IV) contrast administration. Obtained T1- and T2-weighted images were analyzed with computer-aided detection (CAD) image analysis. With the help from a radiologist, the maximum lesion size was read from the B-mode imaging.

Estrogen receptor (ER), progesterone receptor (PR), human epidermal growth factor receptor 2 (HER2), and Ki-67 proliferative index status of the pre-NACT tumor needle core biopsies were obtained from the clinical record. ER and PR were considered negative if less than 1% of invasive tumor cells were immunoreactive, and were considered positive if greater than or equal to 1% of invasive tumor cells were immunoreactive. As per the

American Society of Clinical Oncology (ASCO)/College of American Pathologists (CAP) guidelines [25], immunohistochemical HER2 scores of 0 and 1+ were considered negative and a score of 3+ was scored as positive. Equivocal HER2 immunostains (HER2 scores of 2+) underwent fluorescence in situ hybridization testing for HER2 amplification and were classified as per the ASCO/CAP guidelines. Ki-67 immunostain was reported as a percentage of positively staining nuclei.

Based on the clinical biomarker data, the tumors were divided into five molecular subtypes according to the St. Gallen criteria [26]: Luminal A—ER positive, PR positive/negative, HER2 negative, and Ki-67 < 14%; Luminal B (HER2-)—ER positive, PR positive/negative, HER2 negative, and Ki-67 ≥ 14%; Luminal B (HER2+)—ER positive, PR positive/negative, HER2 positive, and any Ki-67; HER2 positive—ER negative, PR negative, and HER2 positive; and triple-negative (TN)—ER negative, PR negative, and HER2 negative. Among them, Luminal A, Luminal B (HER2-), and Luminal B (HE2+) types were ER-positive tumors.

Statistical analysis

The measured SWS was converted to elasticity expressed in kilopascals [27]. Changes of SWE parameters were also calculated:

$$E_{\text{mean}1-2} = E_{\text{mean}1} - E_{\text{mean}2},$$

$$E_{\text{mean}1-3} = E_{\text{mean}1} - E_{\text{mean}3},$$

$$E_{\text{max}1-2} = E_{\text{max}1} - E_{\text{max}2},$$

$$E_{\text{max}1-3} = E_{\text{max}1} - E_{\text{max}3},$$

$$f_{\text{mass}1-2} = f_{\text{mass}1} - f_{\text{mass}2},$$

$$f_{\text{mass}1-3} = f_{\text{mass}1} - f_{\text{mass}3}.$$

The subscripts 1, 2, and 3 indicate the corresponding parameters measured at the first, the second, and the third visits, respectively.

Statistical analysis was conducted with RStudio (RStudio, PBC, Boston, MA). The Kruskal-Wallis test and Pearson's chi-squared test were used in the statistical analysis to calculate the p value for continuous data and count data, respectively. $p < 0.05$ was considered indicative of a statistically significant difference. Leave-one-out cross-validation (LOOCV) [28] was used to assess the effect of multiple factors on the prediction of the response to NACT. Receiver operating characteristic (ROC) curve analysis was used to calculate the area under the curve (AUC) and determine the cutoff values, as well as the corresponding sensitivity and specificity. The optimal cutoff was defined as the point closest to the point (0, 1) on the ROC curve.

Results

Clinical parameters during the NACT

Patient demographic and tumor characteristics of the 62 patients enrolled in this study are presented in Table 1. Overall, as expected, compared to other histologic subtypes, patients with invasive ductal carcinoma had higher rates of response to NACT ($p = 0.03$), and higher tumor grade (grade III) had a higher response rate of 67.7% compared to 32.3% to lower grade tumors (grade I/II). Among different ER-positive molecular subtypes, a significant difference was found for the response rate ($p = 0.03$) with the highest response rate seen in Luminal B (HER2+) type cancers. Table 2 summarizes the MRI volume (V_{MRI}), mass size (s), and the SWE parameters, including the new parameter f_{mass} . The averaged MRI volume, shear wave elasticity, and mass size decreased during the NACT treatment for both the responder group and the non-responder group. Tumor response was significantly correlated with the values of $E_{\text{mean-ratio}1}$ measured during the first SWE visit; s_2 , $E_{\text{mean}2}$, and $E_{\text{max}2}$ measured during the second SWE visit; and $V_{\text{MRI}3}$, s_3 , $E_{\text{mean}3}$, $E_{\text{max}3}$, $E_{\text{mean-ratio}3}$, $E_{\text{max-ratio}3}$, and $f_{\text{mass}3}$ measured during the third SWE visit.

For all three visits, non-responders showed higher averaged elasticity, elasticity ratio, and lower mass characteristic frequency. No significant difference was found in the change of elasticity, although there was a trend for the averaged change in stiffness in the responder group to be higher. A significant difference was found in the change of the mass characteristic frequency measured between the first and the third visits ($f_{\text{mass}1-3}$, $p < 0.001$). Figures 3 and 4 show the typical SWS maps for a responder and a non-responder for the three SWE studies, respectively; E_{mean} and f_{mass} for different molecular subtypes measured during the three visits are shown in Figs. 5 and 6, respectively, indicating that stiffness decreased significantly for the responders, while remained high for the non-responders; the f_{mass} remained low for non-responders and increased significantly for responders.

Leave-one-out cross-validation for the NACT response prediction

Selected SWE parameters measured at each visit were combined using the LOOCV to predict the NACT treatment response, and the models were denoted as the noninvasive models. The $E_{\text{mean-ratio}1}$ and s_1 were combined for the first visit, the $E_{\text{mean}2}$ and s_2 were combined for the second visit, and the $E_{\text{max-ratio}3}$ and $f_{\text{mass}3}$ were combined for the third visit. The corresponding ROCs are shown in Fig. 7a. The AUCs, optimal cutoffs, and the corresponding specificity and sensitivity are summarized in Table 3. The AUC (0.84, 0.95 CI 0.78–0.97) for the third visit was the highest among the three visits. A

^aData are mean ± standard deviation

* $p < 0.05$; the difference is statistically significant

significant difference was found for the AUC between the first and the third visits ($p = 0.04$). No significant difference was found between the second and the third visits ($p = 0.29$). Therefore, the AUC (0.75, 0.95 CI 0.62–0.88) for the second visit gave the second best prediction, given the balance between timing and accuracy.

For ER-positive tumors, the Ki-67 index obtained from the pre-NACT biopsy was then added to the selected SWE parameters included in the noninvasive models with the LOOCV to predict NACT response. The corresponding models were denoted as the mixed models, with ROCs shown in Fig. 7b. The AUCs, optimal cutoffs, and the corresponding specificity and sensitivity are

summarized in Table 3. Among the mixed models, the ROC for the first visit showed the best prediction (0.80, 0.95 CI 0.65–0.96). With an optimal of 0.68, the specificity was 0.93 and the sensitivity was 0.70.

The AUCs for both the invasive models and the mixed models during the three visits are compared in Fig. 7c. The AUCs for the NACT response prediction with the MRI volume during the three visits were also plotted. The corresponding AUCs were 0.62 (0.95 CI 0.45–0.78), 0.73 (0.95 CI 0.46–1.00), and 0.73 (0.95 CI 0.54–0.92), respectively. No significant difference was found among the three AUCs. Since most patients only had the first MRI imaging before NACT, the number of MRI volume

results available for the second and third visit was relatively small. Therefore, we also included the AUCs of the MRI volume adapted from [24] for reference. In contrast to the calculation method used in this study, tumor volume in [24] was computed by summing all voxels

with percentage enhancement (PE) above a nominal threshold value of 70%, and $PE = ((S_1 - S_0) / S_0) \times 100\%$, where S_0 , S_1 , and S_2 represented the signal intensities on the precontrast, early postcontrast, and late postcontrast images, respectively.

Discussion

The results of our study demonstrate that SWE aids accurate assessment and early prediction of tumor response to NACT; for ER-positive tumors, combining the Ki-67 index with some SWE parameters can further improve the response prediction. Our study showed that

the averaged stiffness decreased for both the responders and the non-responders. Moreover, the changes in stiffness for both the E_{mean} and E_{max} between the first two visits were larger than the changes between the second and the third visits. The slower drop in stiffness during the later course of NACT treatment may be due to hypoxia, which is associated with increased matrix stiffness in the non-necrotic area of the tumors [29, 30].

Moreover, it has been shown that residual tumor appears to be stiffer than the fibrous tissue left for the pCR [22]. These changes in stiffness can also be detected with SWE during the NACT treatment [8, 31].

The f_{mass} is a newly introduced SWE parameter for breast cancer characterization, and a lower f_{mass} value is significantly correlated with poor histologic prognostic factors. The average f_{mass} value for the non-responders stayed relatively constant throughout the NACT treatment. Recalling the definition of f_{mass} , this result

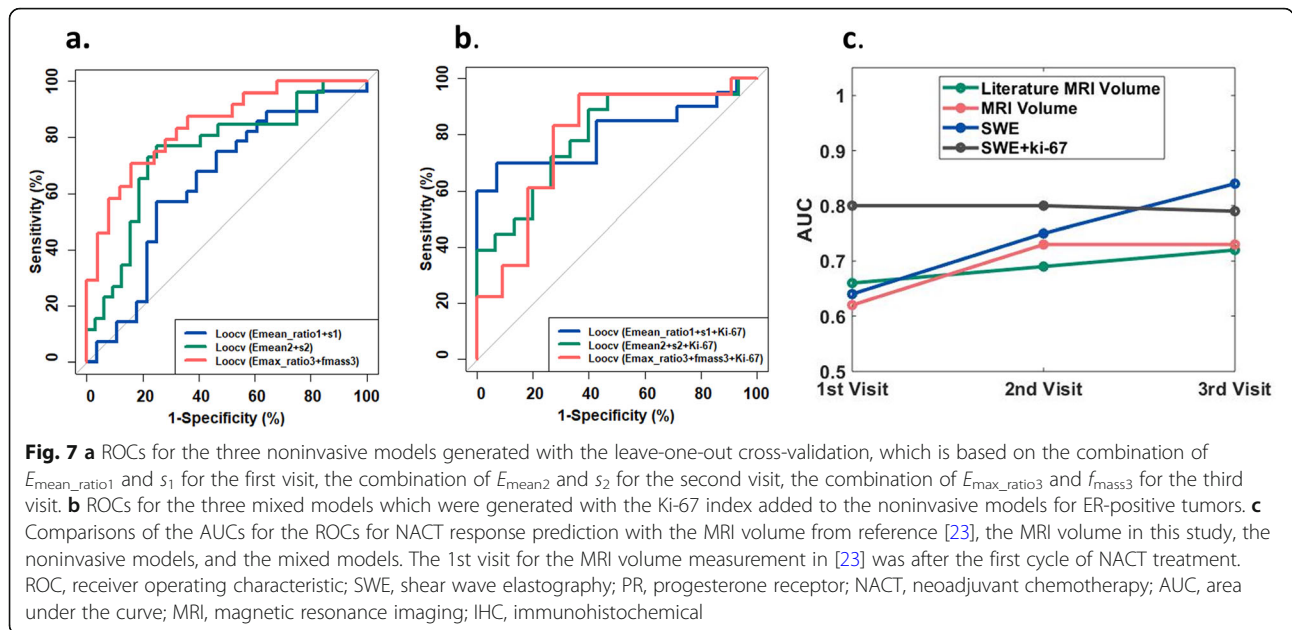

indicated that the change of SWS and mass size during the NACT was such that the net effect on f_{mass} was minimal for the non-responders. This study showed that the averaged f_{mass} for the responders was higher than that for the non-responders during all three visits. For the third visit, a significant difference was found among the responders and non-responders. Among the responders, there was no significant difference between f_{mass1} and f_{mass2} . When compared to the average f_{mass1} , the average f_{mass3} significantly increased by 70%, indicating that the

effect of size reduction was dominant on f_{mass} (compared to the change of minimum SWS) after the mid-course of NACT. A similar trend was observed in each molecular subtype. However, the average E_{mean} decreased continuously throughout the NACT. When compared to the first measurement, the average E_{mean} decreased by 48% during the second visit and by 62% during the third visit. Therefore, f_{mass} could be used as a useful indicator to determine the end-of-treatment point for the NACT for responders. Currently, response to NACT is routinely assessed using MRI, clinical ultrasound, and mammography

[22]. The addition of f_{mass} could further facilitate the individualized NACT treatment plan. We plan to extend our study to a larger number of patients and with more frequent f_{mass} measurements in the course of NACT to further investigate the role of f_{mass} in predicting earlier response to NACT.

Predictions of response to NACT with the noninvasive models which combine the SWE parameters show promising results for all three visits. To balance the timing and accuracy, the parameters obtained during the mid-course of NACT could be used for evaluating the

NACT treatment outcome. Similarly, a previous study showed that the optimal time for early evaluation to identify patients who would be responsive to treatment was after 2 cycles of treatment and immediately before the third cycle of the therapy [29].

The Ki-67 index is an important predictive factor for the effectiveness of NACT [32, 33]. Breast cancer with a high Ki-67 index level has repeatedly been shown to respond better to chemotherapy. A previous study also showed that there was no pathological complete response in cases with $\text{Ki-67} < 25\%$ [34]. In this study, we found that the average Ki-67 value was higher in responders than in non-responders. Mixed models, which combined the Ki-67 index obtained before NACT with the noninvasive models, were proposed for ER-positive tumors. When compared to the noninvasive model for the second visit, an earlier prediction with improved accuracy could be achieved with the mixed model. Similarly, the study by Ma et al. has shown the potential value of

adding Ki-67 to shear wave parameters for better and earlier prediction of the response to therapy [35].

Both the noninvasive models and the mixed models were generated with the leave-one-out cross-validation analysis, which included internal validations to quantify any optimism in the predictive performance and adjust the models for overfittings [36, 37]. Therefore, the models proposed in this paper for predicting the response to NACT have high reproducibility and stability.

Studies showed that MRI volumetric assessment was more accurate than the diameter for earlier detection of treatment response [22, 24]. The volume from clinical MRI was also recorded in this study for all three visits. Though the MRI volume data was limited in this study, the ROCs were comparable to the results from a previous study with a larger patient number. Moreover, both the AUCs from the noninvasive model for the second visit and from the mixed model for the first visit were higher than the MRI volume prediction at the corresponding

Table 3 Summary of the ROCs for the leave-one-out cross-validation analysis

Parameters	AUC	Cutoff	Specificity	Sensitivity
Noninvasive model

time point. However, the results of proposed prediction models could vary among different study populations. Therefore, a future study based on a larger population will be helpful for comparing the results from the MRI prediction and the proposed models in this study.

There are some limitations in this study. Firstly, the sample size was relatively small; moreover, as shown in the flowchart, some patients did not complete all three visits for the SWE studies, leading to some missing data. However, the leave-one-out cross-validation has been applied to compensate for the sample number limitation. Secondly, this is a one-center study. Thus, a multicenter study with a larger population is required to further investigate the role of SWE parameters in NACT response prediction.

In summary, this study investigated the application of SWE in discriminating the responders from non-responders to chemotherapy, before NACT, during the mid-course of NACT, and after NACT but prior to surgery. In conclusion, when the noninvasive model is used for response prediction, a balance between the timing and accuracy is achieved when the $E_{\text{mean}2}$ and s_2 are measured during the mid-course of the treatment. For ER-positive tumors, an even earlier and more accurate response prediction could be obtained with the combination of Ki-67 index, $E_{\text{mean_ratio}1}$, and s_1 measured before the treatment using the mixed model. Moreover, this study also shows that f_{mass} is useful in determining the endpoint of the NACT.

Conclusions

Our study findings highlight the value of SWE estimation in the mid-course of NACT for the early prediction of treatment response. For ER+ tumors, the addition of Ki-67 improves the predictive power of SWE. Moreover, f_{mass} is presented as a new marker in predicting the endpoint of NACT in responders. These results may facilitate personalizing the treatment regimens of patients with breast cancer receiving NACT. Furthermore, the role of these SWE parameters can be validated in the future by carrying out a multicenter prospective study with a larger patient population.

Acknowledgements

The authors would like to thank Dr. Mahdi Bayat, PhD; Dr. Viksit Kumar, PhD; Dr. Bae-Hyung Kim, PhD; Dr. Rohit Nayak, PhD; Dr. Saba Adabi, PhD; Dr. Redouane Ternifi, PhD; Mr. Jeremy Webb; and Ms. Yinong Wang for their

assistance in SWE data acquisition at different time periods during the course of the study. Also, we thank Mr. Duane Meixner, R.V.T., R.D.M.S., and Ms. Kate Knoll, R.V.T., R.D.M.S., for patient scanning and Ms. Cindy Andrist for her valuable help in patient recruitment. The authors are also thankful to Dr. Sonia Watson, PhD, for her editorial help.

Authors' contributions

Study conception and design: AA and MF. Methodology: AA and MF. Software: JG. Validation: AA, MF, RTF, SP, JCB, JMC, ECP, and JG. Formal analysis: JG and ECP. Investigation: AA, MD, JG, and AVG (performing the data acquisition/collection). Resources: AA, MF, and RTF. Data curation: JG. Writing—original draft: JG. Critical revision: JMC, JCB, MF, AA, JG, RTF, SP, and ECP. Visualization: JG. Supervision: AA and MF. Project administration: AA and MF. Funding acquisition: AA and MF. All the authors read and approved the final manuscript.

Authors' information

Note: Currently, Dr. Max Denis is with the University of the District of Columbia, and Ms. Adriana Gregory is with the Nephrology Research at the Mayo Clinic.

Funding

The study was supported by grants from the National Cancer Institute, National Institutes of Health: R01CA148994, R01CA148994-S1, R01CA195527, and R01CA168575. The content is solely the responsibility of the authors and does not necessarily represent the official views of NIH. The NIH did not have any additional role in the study design, data collection and analysis, decision to publish, or preparation of the manuscript.

Availability of data and materials

The datasets used and/or analyzed during the current study are available from the corresponding author on reasonable request.

Declarations

Ethics approval and consent to participate

This prospective study was Health Insurance Portability and Accountability Act (HIPAA) compliant and was approved by the Institutional Review Board (IRB) (IRB application #12-003329).

Consent for publication

Signed IRB-approved informed consent with permission for publication was obtained from all individual participants included in the study.

Competing interests

The authors declare that they have no known competing financial interests or personal relationships that could have appeared to influence the work reported in this paper. Although the research was supported by the grant from NIH, NIH did not have any additional role in the study design, data collection and analysis, decision to publish, or preparation of the manuscript.

Ready to submit your research? Choose BMC and benefit from:

- fast, convenient online submission
- thorough peer review by experienced researchers in your field
- rapid publication on acceptance
- support for research data, including large and complex data types
- gold Open Access which fosters wider collaboration and increased citations
- maximum visibility for your research: over 100M website views per year

At BMC, research is always in progress.
