ABSTRACT

The leopard, *Panthera pardus*, is a threatened species in its range throughout the world. Although, historically, the Korean Peninsula had a high population density of leopards, they were extirpated from South Korea by 1970, leaving almost no genetic specimens. Traditionally, Korean leopards are classified as *Panthera pardus orientalis*; however, their classification is based only on locality and morphology. Therefore, there is a need for genetic studies to identify the phylogenetic status of Korean leopards at the subspecies level. Presently, no extant wild specimen is available from South Korea; therefore, we extracted genetic material from the old skin of a leopard captured in Jirisan, South Korea in the 1930s and conducted the first phylogenetic study of the South Korean leopard. A total of 726 bp of mitochondrial DNA, including segments of the NADH5 and control region, were amplified by PCR. A phylogenetic analysis of the fragment, along with sequences of nine leopard subspecies from GenBank revealed that the extinct South Korean leopard belonged to the Asian leopard group and in the same clade as the Amur leopard (*Panthera pardus orientalis*). Thus, the leopard that inhabited South Korea in the past was of the same subspecies as the Amur leopard population currently inhabiting the transboundary region of Russia, China, and North Korea. These results emphasize the importance of conserving the endangered wild Amur leopard population (estimated to be about 60–80 individuals) in Russia and China, for future restoration of leopards in the Korean Peninsula.

INTRODUCTION

The leopard, *Panthera pardus*, is a generalist carnivore among the large cat species and was historically distributed throughout a large part of the world (Nowell & Jackson, 1996; Jacobson et al., 2016). The leopard population has undergone a rampant decrease over the years and is on the brink of extinction in many regions due to human threats such as

overhunting, poaching and habitat loss and fragmentation (Jacobson *et al.*, 2016). Leopards were once found throughout the Korean peninsula in the past and were sometimes referred to as the Korean leopard (Ognev, 1962; World Wildlife Fund (WWF), 2019).

Throughout Asia, leopards were considered harmful animals that threatened public safety and their skins were mainly collected as tributes and trophies in the past (Jacobson *et al.*, 2016; Jo & Baccus, 2016). These animals were systematically captured over a long period of time, from the Joseon dynasty (1392–1910) through the Japanese colonial period (1910–1945). The annual number captured decreased rapidly in the early 20th century and eventually, they were difficult to find in the Korean peninsula by the end of the Japanese colonial period (Jo & Baccus, 2016). Historical records indicate that at least 624 leopards were killed under the policy of eliminating harmful animals during the Japanese occupation (Governor-General of Korea, 1917, 1926, 1942; Endo, 2009, 2014). There have been informal eyewitness accounts of leopards until the 2000s (Jo, 2008; Nam, 2012), but formally the last wild leopard in South Korea was captured and photographed in Yeohangsan in 1970 (Chosun Ilbo, 1970; Kyunghyang Shinmun, 1970). The International Union for Conservation of Nature (IUCN) considers that the leopard has been extinct in South Korea and estimates the extinction occurred after 1969 but the exact time is not known because tracks have been seen after that (Nowell & Jackson, 1996; Stein *et al.*, 2016).

The tiger is another large feline species that was also extirpated from South Korea. A phylogenetic study of Korean tigers was conducted using skull and bone specimens from Japan's National Science Museum and the Smithsonian Museum in the USA (Lee *et al.*, 2012). Hides are a common form of preservation of mammalian specimens, both in museum collections and as trophies (Hedmark & Ellegren, 2005). Thus, specimens from museums and private collections might be available for DNA analysis of extinct carnivores. Unfortunately, when the leopard became extinct in South Korea, there were almost no remains left of the leopard from which genetic specimens could be extracted. However, we discovered an old leopard skin in South Korea and herein present a phylogenetic analysis using DNA samples extracted from this specimen.

There are nine subspecies of leopards in the world (Miththapala, Seidensticker & O'Brien, 1996; Uphyrkina *et al.*, 2001). Recently, phylogenetic relationships of the leopards have been refined by analyzing additional samples from previously uncovered areas (Rozhnov, Lukarevskiy & Sorokin, 2011; Farhadinia *et al.*, 2015; Wilting *et al.*, 2016). However, genetic studies on the subspecific classification of the historical leopard population in South Korea have not yet been performed. Such information is vital for formulating restoration and management strategies aimed at restoring or reviving extirpated species in a region. A previous study on the leopard subspecific phylogeny used only North Korean samples (Uphyrkina *et al.*, 2001) and genome research conducted in South Korea used an Amur leopard sample from a zoo (Kim *et al.*, 2016). Although leopards in South Korea are classified as the Amur leopard subspecies *P. pardus orientalis* (Jacobson *et al.*, 2016), their classification is based only on sample locality and morphology information. Therefore, identification of the phylogenetic status of Korean leopards

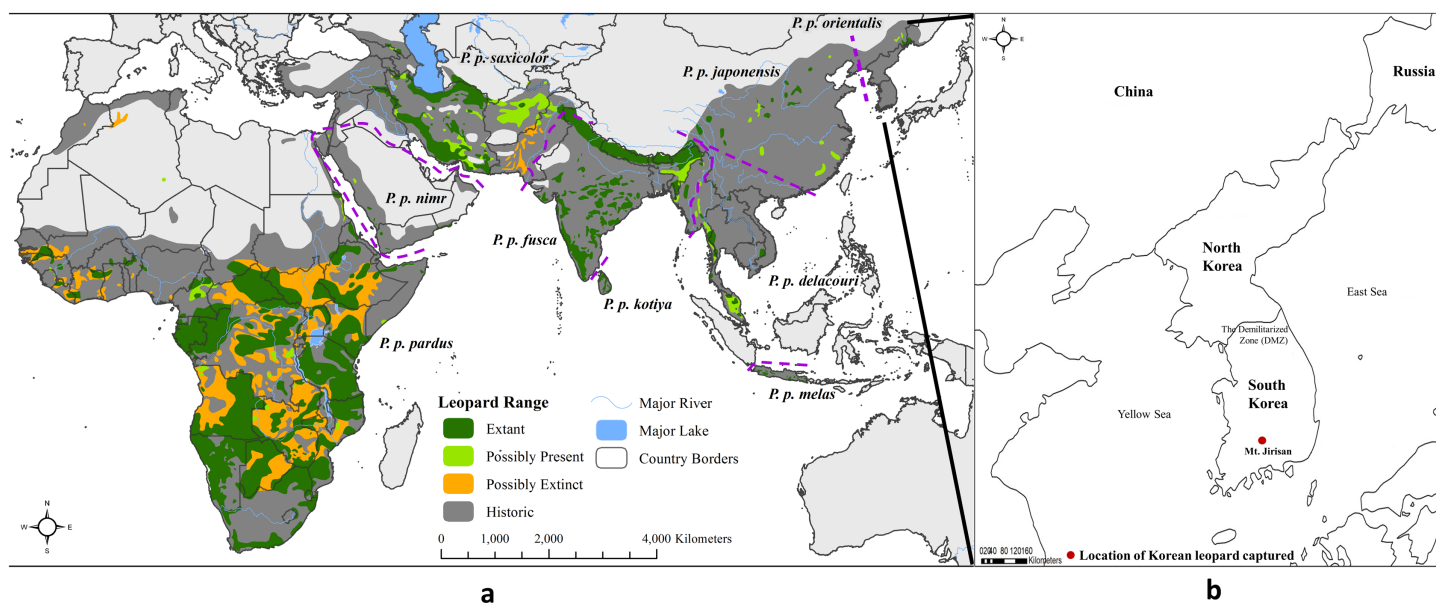

Figure 1 Distribution map of leopard subspecies and sample information. (A) Distribution of leopard subspecies (source: [Jacobson et al., 2016](#)). (B) Capture location of leopard specimen used in this study. [Full-size](#) DOI: [10.7717/peerj.8900/fig-1](https://doi.org/10.7717/peerj.8900/fig-1)

based on genetic studies is important to document the subspecific status of leopards in South Korea.

In this study, we obtained genetic material from the old skin of a leopard captured in Jirisan, South Korea in the 1930s and conducted a phylogenetic study to identify the subspecific status of leopards in South Korea, an important historical habitat of this large carnivore.

MATERIALS AND METHODS

Sample collection

Due to the limited South Korean leopard samples left, we could collect only one specimen. Although limited in quantity, it might be a suitable specimen to determine the phylogenetic position of Korean leopards since the specimen was originated from the southern tip of the Korean Peninsula ([Fig. 1](#)). The sample was donated to and stored in Conservation Genome Resource Bank for Korean Wildlife (CGRB) at Seoul National University, Republic of Korea (<http://www.cgrb.org>). The registration number was CGRB15834.

The specimen was a skin rug of a Korean leopard caught by a Korean hunter in Jirisan, South Korea, in 1935 during the period of Japanese occupation. Genetic samples were collected from this skin rug. Considering the difficulty of extracting DNA from old skins ([Moraes-Barros & Morgante, 2007](#)), we sampled various sites of the leopard specimen, including the foot pad, claw, ear and nose. Only the internal portions of each part were collected to avoid any contamination due to external exposure during long-term storage.

DNA extraction, polymerase chain reaction and sequencing

DNA was extracted using the QIAGEN QIAamp DNeasy Blood & Tissue Kit (Qiagen, Hilden, Germany). Initially, we performed PCR amplification using the leopard species-specific primer set Ppo_CbF/Ppo_CbR (Ppo_CbF: 5'-GTAAATTATGGCTGAATTATCCGG-3', Ppo_CbR: 5'-CATAACCGTGAACAATAATACGAC-3') (Sugimoto *et al.*, 2006) to amplify a 156 bp DNA fragment of cytochrome *b*, to check the success of DNA extraction from the old skin.

Three primer sets were used for PCR amplification of two segments of mitochondrial DNA (total of 726 bp), including the NADH dehydrogenase subunit 5 (NADH5) gene (611 bp) and control region (CR) gene (115 bp). We used two primer sets, F/RL2 and F2/RL4 (F: 5'-GTGCAACTCCAAATAAAAG-3', RL2: 5'-TAAACAGTTGGAACAGGTT-3', FL2: 5'-CGTTACATGATCGATCATAG-3', RL4: 5'-TTAGTTTTTCGTGTTGGGT-3') (Uphyrkina *et al.*, 2001), each of which amplified approximately 400 bp of the NADH5 mitochondrial gene. In the Uphyrkina *et al.* (2001) study, there was not enough information on the primers for the control region, so we designed a primer set CR_PP_F/CR_PP_R (CR_PP_F: 5'-CCTCAACTGCCCGAAA-3', CR_PP_R: 5'-CATGGCCCTGAAGTAAGAA-3') to amplify the targeted 115 bp segment of the CR gene.

The PCR included a final reaction volume of 15 μ L containing 10 \times PCR buffer (iNtRON Biotechnology, Inc., Gyeonggi-do, South Korea), 0.2 mM dNTP, 0.75 μ M of each primer, 9 μ g of bovine serum albumin (BSA), 0.375 units of Taq DNA polymerase (iNtRON Biotechnology, Inc., Gyeonggi-do, South Korea), and three μ L of template DNA. PCR cycling conditions were as follows: 5 min initial denaturation at 94 $^{\circ}$ C; 45 cycles of 0.5 min denaturation at 94 $^{\circ}$ C, 0.5 min annealing at 56 $^{\circ}$ C for *cyt b* or 53 $^{\circ}$ C for CR and 45 s extension at 72 $^{\circ}$ C; and a final extension for 10 min at 72 $^{\circ}$ C. Reaction conditions for the NADH5 gene were as follows: 5 min initial denaturation at 94 $^{\circ}$ C; 45 cycles of 0.5 min denaturation at 94 $^{\circ}$ C, 1.5 min annealing at 50 $^{\circ}$ C, 1 min extension at 72 $^{\circ}$ C; and a final extension for 10 min at 72 $^{\circ}$ C. PCR was conducted on a TaKaRa PCR thermal cycler dice (TaKaRa, Tokyo, Japan). A total of three μ L of the PCR products were electrophoresed on 1% agarose gel in 0.5 X Tris–borate–EDTA (TBE) buffer. Purification was performed using a Zymoclean Gel DNA Recovery kit (Zymo Research, Irvine, CA, USA). Each step of experimentation included a negative control to prevent contamination and a positive control of a tissue sample from a naturally dead leopard in a zoo to ensure adequate conditions for successful experiments. The NADH5 and CR segments were sequenced in both forward and reverse directions using the BigDye Cycle Sequencing Kit version 3.1 on an ABI 3700xl sequencer analyzer (Applied BiosystemsTM, Foster City, CA, USA). DNA sequence data of the Korean leopard were deposited into GenBank (accession number: [MK114159–MK114160](#)).

Data analysis

The final nucleotide sequence of each NADH5 and CR segment was determined by the assembly of both direction sequences using Geneious Pro 5.3 software (Kearse *et al.*, 2012). For the phylogenetic analysis, representative haplotype sequences of all leopard subspecies (Uphyrkina *et al.*, 2001; Wilting *et al.*, 2016) were downloaded

from NCBI (accession numbers [AY03522–AY035292](#) and [JN811043–JN811046](#)). For an outgroup, sequences from *Panthera tigris* ([KJ508412–KJ508413](#)) were used. The nucleotide sequences of the Korean leopard, nine subspecies of leopard, and the tigers were aligned together using the Geneious alignment option implemented in Geneious Pro v 5.3 ([Kearse et al., 2012](#)) (<http://www.geneious.com>). Concatenated sequences (726 bp) of NADH5 and CR for all samples were used for phylogenetic tree construction.

Phylogenetic trees were constructed by maximum likelihood (ML) analysis in MEGA 6.0 ([Tamura et al., 2013](#)) with 10,000 bootstrap replicates and the HKY + G + I model of sequence evolution following a Bayesian Information Criterion (BIC) model of selection ([File S1](#)). MrBayes v3.2 ([Ronquist & Huelsenbeck, 2003](#)) and BEAST v1.7.4 ([Drummond et al., 2012](#)) were also used to construct phylogenetic trees using Bayesian inference (BI) with the HKY + G + I model, which was found to be the most suitable using the jModeltest 2.1.10 software. In BEAST, Bayesian analysis was conducted using an uncorrelated lognormal relaxed clock model and Markov Chain Monte Carlo (MCMC) chain lengths of 10,000,000 iterations and every 1,000th tree was logged. The Figtree v1.3.1 software was used to visualize the trees (<http://tree.bio.ed.ac.uk/software/figtree>). Network analysis for the mtDNA sequence data was conducted using the NETWORK v5.0.0.3 software package ([Bandelt, Forster & Rohl, 1999](#)).

RESULTS

In this study, DNA from an old skin of the Korean leopard was successfully extracted and targeted fragments of NADH5, CR and cytochrome *b* were amplified from mitochondrial DNA. The primer Ppo_Cb successfully amplified the cytochrome *b* fragment from DNA extracted from the inside of the claw, ear and foot pad. However, the relatively long fragment (~400 bp) of the NADH5 region was amplified only from the DNA extracted from the claw. A comparison of the concatenated nucleotide sequences of the Korean leopard and nine leopard subspecies revealed a new haplotype (KOR1) in the Korean leopard. Among the nine leopard subspecies, the South Korean leopard showed the highest genetic similarity with two haplotypes of Amur leopard (ORI1, ORI2) from North Korea and Russia. KOR1 differed from ORI2 in only two nucleotide sites—one in the NADH5 segment (position 189 of the concatenated sequences) and the other in the CR segment (position 725 of the concatenated sequences) ([Table 1](#)).

The phylogenetic relationships among the leopard subspecies were similar among ML trees. The ML tree supported the division of leopards into nine subspecies, except that the North Chinese leopards (JAP) and Persian leopards (SAX) were not grouped into a single clade. The African leopard (SHO) was divided into two sub-groups. The Korean leopard was grouped into the Amur leopard (ORI) lineage ([Fig. 2A](#)). Three subspecies (ORI, JAP and DEL) with ranges in the eastern and southeastern parts of continental Asia were grouped together, including the Korean and Amur leopards. This clade was included in the larger Asian leopard group. MEL from Java was more closely related to the Asian group than the African.

We used two independent software packages to construct the Bayesian tree using the same nucleotide substitution. The tree topology obtained using MrBayes was not

Table 1 Polymorphic sites of mitochondrial NADH5 and control region (CR) partial genes of leopards (*Panthera pardus*) from South Korea and position number is from the beginning of concatenated sequences of NADH5 and CR.

Full-size [DOI: 10.7717/peerj.8900/fig-2](https://doi.org/10.7717/peerj.8900/fig-2)

consistent with the geographical distribution (File S2) of defined leopard subspecies. The results of the Bayesian phylogenetic analysis using BEAST clustered different subspecies into its own subclade and are shown in Fig. 2B. The leopard subspecies formed three distinct clusters corresponding to Asian, Javan and African + Arabian distributions. Among the Asian leopards, the Korean leopards (KOR1) and Amur leopards (ORI1 and ORI2) were grouped into a single clade. In general, the Korean leopard belonged to the Asian group and formed the same lineage as the Amur leopard in both ML and Bayesian trees with support values of 53% (bootstrap) and 0.79 (posterior probability), respectively (Fig. 2).

Network analysis revealed that Asian, Javan, and African + Arabian leopard groups constituted three major clusters (Fig. 3). Samples from each subspecies within the Asian group were grouped together according to geographic proximity (ORI, DEL, FUS, JAP, KOT and SAX). The network analysis was in agreement with the results from the phylogenetic tree reconstructions.

DISCUSSION

It is difficult to extract DNA from ancient samples due to risk of loss from degradation and breakage (Hall, Willcox & Jones, 1997; Pääbo et al., 2004; Moraes-Barros & Morgante, 2007).

DNA extraction from the claws of carnivorous trophy skins is most efficient for genetic studies (Hedmark & Ellegren, 2005). In this study, DNA was also extracted successfully from the claws of the South Korean leopard hide and more than 600 base pairs of the mitochondrial DNA were amplified.

Phylogenetic status of Korean leopard

Phylogenetic reconstructions in this study demonstrated that leopards are divided into three major groups, corresponding to Asian, Javan, and African + Arabian distributions. This result is similar to recent studies on leopard phylogeny (Wilting *et al.*, 2016), where the authors suggested classifying leopards into three groups. More specifically, looking into the BI, the leopard subspecies formed two major clusters: (1) larger Asian group and Javan and (2) African and Arabian. ML and BI topology are similar in this study and they both supported well the nine subspecies divided in the previous study (Uphyrkina *et al.*, 2001). The position of the Arabian leopard (NIM) is slightly different between ML and BI, which was also reported in previous studies (Farhadinia *et al.*, 2015; Uphyrkina *et al.*, 2001; Wilting *et al.*, 2016). Sometimes it was included within the African clade and at other times, it was independent of Africa. These conflicting results might be due to a low resolution caused by short length of sequences and small sample size and further study is therefore required to resolve this issue.

All phylogenetic trees showed that the South Korean leopard was tied to the same lineage as the Amur leopard in the Asian group. In the Asian group, clades reflected

subspecific classifications, except for JAP. The clades of three subspecies (ORI, DEL, JAP), which are distributed geographically from eastern to southeastern Asia, were observed as one cluster in the ML and BI phylogeny. The Amur leopard to which the South Korean leopard belongs, was clustered with the Asian group and the East Southern Asian group. Leopard subspecies that are distributed geographically more closely in East and Southeast Asia are genetically closer (Fig. 1). Although the clustering pattern of some Asian subspecies is not clear in the ML and BI tree to distinguish the subspecies (JAP, FUS and SAX), the tree topology clearly assigned the South Korean leopard (KOR) and Amur leopard (ORI) to the same clade.

In our study, it was difficult to clearly distinguish subspecies of Asian leopards because branch lengths were short. A possible reason for this may be that the information contained in the target sequence used in the analysis was insufficient to classify the subspecies. Recently, the Cat Specialist Group of IUCN/SSC suggested that there are eight subspecies of leopard, excluding *P. p. japonensis* which was merged with *P. p. orientalis* (Kitchener et al., 2017). Regardless, in the phylogenetic trees from both the ML and Bayesian analyses of this study, the Korean leopard was placed in the same lineage as the Amur leopard. The results of present genetic study is in agreement with the general expectation that there is no biogeographic barrier between the Northeast Asian Continent and Korean Peninsula that may inhibit dispersal of leopards and gene flow between the populations in these regions. Therefore, we propose that the Korean leopard and the Amur leopard belong to the same subspecies and is part of the Asian group. However, such interpretation needs to be taken with a caution since the phylogenetic relationship was explored based on a single specimen as a potential Korean leopard and larger sample sizes would reveal a level of variation among sequences from different individuals. Given the limited sample size in this study, a comprehensive study using more samples would be useful in clarifying subspecific status of Korean leopard within the Asian group.

Conservation and restoration of the Korean leopard

The present results suggest possible directions for the future restoration of leopards in the Korean Peninsula. There seem to be two ways to restore the leopard population in the Korean Peninsula. One possible way is the reintroduction of leopards into the South Korean region using captive-bred Amur leopard individuals. A similar proposal has been made to reintroduce leopards into the southern Sikhote-Alin region (Kelly, Stack & Harley, 2013; Hebblewhite et al., 2011). Previous studies suggest that the reintroduction of leopards, which are relatively safer than tigers, might be possible and the best area for this would be Kangwon province, which includes the Korea demilitarized zone (DMZ) (Jeon, Lee & Kang, 2009; Lim, 2017). Amur leopards use smaller home ranges (33–139 km² for a female leopard) than Amur tigers (384 km² for tigress) and are nonexclusive (Salmanova, 2008; Goodrich et al., 2010; Lee et al., 2013; Spitzen et al., 2013). In addition, due to their smaller body size and lower energy requirements, Amur leopards are expected to be in less conflict with humans than Amur tigers (Goodrich et al., 2011; Spitzen et al., 2013). For the initial reintroduction of leopards, previous studies proposed the area near the eastern part of the DMZ because of its low human population density

and high density of prey animals such as ungulates (Choi, 2005; Jeon *et al.*, 2008; Jeon, Lee & Kang, 2009; National Institute of Environmental Research, 2013; Choi, 2015). The DMZ region is a part of the major ecological network of the Korean Peninsula. This area consists of high mountains and a dense temperate forest, which are important habitats for wildlife (Lim, 2017).

IUCN guidelines for reintroduction highlight the importance of sourcing founders from genetically close populations (IUCN, 1998). Based on our findings that the extinct Korean leopard and the Amur leopard belong to the same subspecies, the Amur leopard is an ideal candidate for a restoration project. We propose to consider carefully planning a reintroduction program for leopards in South Korea using individuals from a captive population of Amur leopard currently managed globally within the Amur Leopard Global Species Management Plan (GSMP), coordinated by the World Association of Zoos and Aquariums (World Association of Zoos and Aquariums (WAZA), 2019). The Amur leopard GSMP manages four regional captive populations (EAZA, EARAZA, AZA and JAZA) globally and 209 individual leopards descended from 13 founders distributed in 88 institutions in the world as of April 2013. The current size of the global wild population of Amur leopards is estimated to be less than 100 individuals (Vitkalova *et al.*, 2018), and this number is too small to be utilized for translocation for a reintroduction program. Therefore, the translocation of wild individuals is not currently an option for a potential reintroduction program. However, since the global captive populations of Amur leopard GSMP are scientifically managed based on conservation genetics principles and metapopulation theory (Leus, Traylor-Holzer & Lacy, 2011), and the captive Amur leopard population belongs to the same genetic lineage as the historical leopard population that inhabited the Korean Peninsula, the GSMP population is well suited to a future reintroduction program in South Korea. The potential reintroduction program could be designed following the reintroduction strategy developed to increase wild Amur leopard populations in the Russian Far East as a model (Kelly, Stack & Harley, 2013). Rigorous assessments of potential habitat, human-leopard conflict issues and disease risks, in addition to the social and financial support needed for success, will be essential components of developing a viable reintroduction program (Hebblewhite *et al.*, 2011; Kelly, Stack & Harley, 2013).

Another way of leopard restoration in the Korean Peninsula is through the natural dispersal of leopard individuals into North Korean territory. The size of the wild Amur leopard population in the Russian-Chinese-North Korean transboundary region has increased rapidly in recent years from approximately 30 to 80, thanks to the intensive cooperative conservation efforts between China and Russia. The Land of the Leopard National Park in the very southern part of Primorsky Krai, Russia serves as the main stable habitat supporting the global increase in leopard population (Jackson & Nowell, 2008; Sugimoto *et al.*, 2014; Xiao *et al.*, 2014; Qi *et al.*, 2015; Vitkalova *et al.*, 2018). Natural dispersal of individuals from this growing wild leopard population may result in range expansion of leopards into North Korean territory in the northern part of the Korean peninsula. Intimate cooperation among North Korea, China and Russia to implement habitat and population conservation measures will be essential for the natural restoration and maintenance of a stable leopard population in North Korea.

CONCLUSIONS

South Korea is in the process of restoring endangered wildlife such as Asiatic black bears, gorals and foxes (*Ministry of Environment in Korea, 2010*), and conducted a basic study on the possibility of the restoration of tigers in Korea (*Lee et al., 2013*). Efforts to restore endangered species in many parts of the world are underway, including the Amoy tiger in China, the cheetah and lion in Africa, the brown bear and lynx in Europe, the wolf in Canada, the cougar and black bear in the USA, and so on (*Wotschikowsky & Kerger, 1990; Breitenmoser et al., 1999, 2014; William & Robert, 2004; Ueda, 2008*). In Russia, besides the Land of the Leopard National Park, a restoration project is underway to reintroduce the Amur leopard into the Lazo Nature Reserve, a former habitat of leopards (*Christie, Cook & Arzhanova, 2012; Spitzin et al., 2012; Kelly, Stack & Harley, 2013*). Like these, in situations where humans are endeavoring to restore endangered species, phylogenetic studies are the fundamental step and important. For successful restoration of endangered species, the first task should be to clarify the taxonomic status of that species. For example, genetic studies were carried out to confirm the phylogenetic position and genetic diversity of reintroduced individuals in the case of the Asiatic black bear, which has been successfully restored in Korea (*Kim et al., 2011*). Our phylogenetic study suggested that the extinct leopards formerly occupying the Korean peninsula belong to the Amur leopard subspecies (*P. pardus orientalis*) currently inhabiting Far East Russia.

Based on the results of this study, we suggest introducing Amur leopard pedigree individuals when attempting to reintroduce leopards into South Korea in the future. The restoration of the leopard in North Korea can be expected through the natural influx of wild Amur leopard populations across the Far East Russia-China-North Korea border. However, an eco-corridor may be needed to facilitate this natural range expansion. Above all, the Amur leopard in the wild is still a critically endangered subspecies, with only 60–80 individuals worldwide (*Jackson & Nowell, 2008; Sugimoto et al., 2014; Xiao et al., 2014; Qi et al., 2015; Vitkalova et al., 2018*). Conservation and increase of this population, which eventually could become a source population for the restoration of leopards in the Korean peninsula, is of utmost importance.

ACKNOWLEDGEMENTS

We gratefully acknowledge Dr. Thomas W. Sappington (USDA-ARS-CICGRU, USA) for editing English and providing comments on this manuscript. The authors would like to thank Dr. Randeep Singh (Amity University, India) for GIS related technical help.

ADDITIONAL INFORMATION AND DECLARATIONS

Funding

This work was supported by the SNU Brain Fusion Program of the Seoul National University under Grant number 2014/550-20140052. This study was partially supported by the Research Institute for Veterinary Science, Seoul National University. The funders had no role in study design, data collection and analysis, decision to publish, or preparation of the manuscript.

Grant Disclosures

The following grant information was disclosed by the authors:

SNU Brain Fusion Program of the Seoul National University: 2014/550-20140052.

Research Institute for Veterinary Science, Seoul National University.

Competing Interests

Tiger and Leopard Conservation Fund in Korea (KTLCF) is a nonprofit, non-governmental organization that started as a small civic gathering to help conserve Amur tigers and leopards. All the fund of KTLCF is donations from members and all of the authors affiliated with KTLCF, Jee Yun Hyun, Jang Hyuk Cho, Puneet Pandey, and Hang Lee, are not employed by KTLCF, but are volunteers who serves for KTLCF but receives no compensation from KTLCF. KTLCF is supporting the conservation of Amur leopard and tiger in Russia, doing research on history of relationship between tigers/leopards and Korean people, and educating people to conserve wildlife.

Author Contributions

- Jee Yun Hyun conceived and designed the experiments, performed the experiments, analyzed the data, prepared figures and/or tables, authored or reviewed drafts of the paper, and approved the final draft.
- Jang Hyuk Cho conceived and designed the experiments, authored or reviewed drafts of the paper, and approved the final draft.
- Puneet Pandey analyzed the data, prepared figures and/or tables, authored or reviewed drafts of the paper, and approved the final draft.
- Mi-Sook Min analyzed the data, authored or reviewed drafts of the paper, and approved the final draft.
- Kyung Seok Kim analyzed the data, authored or reviewed drafts of the paper, and approved the final draft.
- Hang Lee conceived and designed the experiments, authored or reviewed drafts of the paper, and approved the final draft.

Data Availability

The following information was supplied regarding data availability:

The Korean leopard NADH5/CR partial sequences are available at GenBank: [MK114159](#) to [MK114160](#).

The Korean leopard specimen was donated to and is being stored in the Conservation Genome Resource Bank for Korean Wildlife (CGRB) at Seoul National University, Republic of Korea. This specimen can be accessed by contacting CGRB (www.cgrb.org) and submitting the application form. This sample's registration: CGRB 15834.

Supplemental Information

Supplemental information for this article can be found online at <http://dx.doi.org/10.7717/peerj.8900#supplemental-information>.
