ABSTRACT: Methylmercury (MeHg) contamination in rice via paddy soils is an emerging global environmental issue. An understanding of mercury (Hg) transformation processes in paddy soils is urgently needed in order to control Hg contamination of human food and related health impacts. Sulfur (S)-regulated Hg transformation is one important process that controls Hg cycling in agricultural fields. In this study, Hg transformation processes, such as methylation, demethylation, oxidation, and reduction, and their responses to S input (sulfate and thiosulfate) in paddy soils with a Hg contamination gradient were elucidated simultaneously using a multi-compound-specific isotope labeling technique (²⁰⁰Hg^{II}, Me¹⁹⁸Hg, and ²⁰²Hg⁰). In addition to Hg^{II} methylation and MeHg demethylation, this study revealed that microbially mediated reduction of Hg^{II}, methylation of Hg⁰, and oxidative demethylation—reduction of MeHg occurred under dark conditions; these processes served to transform Hg between different

species (Hg⁰, Hg^{II}, and MeHg) in flooded paddy soils. Rapid redox recycling of Hg species contributed to Hg speciation resetting, which promoted the transformation between Hg⁰ and MeHg by generating bioavailable Hg^{II} for fuel methylation. Sulfur input also likely affected the microbial community structure and functional profile of Hg^{II} methylators and, therefore, influenced Hg^{II} methylation. The findings of this study contribute to our understanding of Hg transformation processes in paddy soils and provide much-needed knowledge for assessing Hg risks in hydrological fluctuation-regulated ecosystems.

KEYWORDS: Hg transformation, sulfur amended, paddy soil, multi-compound-specific isotope labeling

1. INTRODUCTION

Over the last few decades, mercury (Hg) cycling in hydrological fluctuation-regulated ecosystems (e.g., wetlands, hydroelectric reservoirs, and paddy soils) has gained extensive attention. This is because, in these ecosystems, inorganic Hg is more readily transformed into toxic and bioaccumulative methylmercury (MeHg), as compared to other ecosystem types. 1-7 As a type of wetland, rice paddy fields play an important role in human MeHg exposure, especially in Hgcontaminated areas.^{8,9} This is because rice (Oryza sativa L.) bioaccumulates MeHg^{10,11} and paddy soil is a unique source of MeHg in rice. 12-16 Since rice is a staple food for a large proportion of the population worldwide, MeHg-contaminated rice and the resulting MeHg exposure risks are recognized as a global issue. 17-19 Therefore, a comprehensive understanding of the biogeochemical cycling of Hg in paddy soils is urgently required.

The transformation of Hg species in rice paddy ecosystems plays a vital role in Hg bioaccumulation and associated human exposure risks. Of particular importance are Hg methylation, demethylation, reduction, and oxidation; most of these processes are predominantly mediated by microorganisms. Existing studies have mostly focused on methylation and demethylation, 3,4,21,22 with little attention paid to the

reduction and oxidation processes. Thus, at present, we have an incomplete picture of Hg cycling in rice paddy soils. How redox processes affect (de)methylation remains unclear. Furthermore, most existing studies have only investigated bulk concentration changes in Hg species in rice paddies, with little study of interconversion processes.^{3,4,23,24} Again, this has limited our understanding of net MeHg production mechanisms. Several studies have spiked stable Hg isotope tracers into rice paddy systems to simultaneously trace different transformation processes, including methylation and demethylation, 3,4,22,25 partitioning and redistribution, 26 and rice plant uptake and translocation. 15,27,28 However, only HgII or MeHg tracers have been applied to date, and only isotopic signals of THg or MeHg were measured in these studies. As a result, the redox processes of Hg in rice paddy systems have not yet been precisely traced.

Wetlands are vital to the coupled biogeochemical cycles of Hg and sulfur (S).²⁹ On the one hand, sulfate reduction to sulfide and sulfide re-oxidation control the speciation and bioavailability of Hg by forming Hg-S compounds.²⁹⁻³¹ Recent studies have confirmed that the bioavailability of Hg substrates in methylation is determined not only by the formation of dissolved Hg-S complexes [e.g., $Hg(SH)_2$, HgS_2H^- , HgS_2^2 , $Hg(SR)_2$, etc.]^{30,31} but also by the intracellular dissolution of HgS nanoparticles. 25,32-34 On the other hand, sulfate reduction mediated by microorganisms is an important pathway for Hg methylation in natural environments.³⁵ For the reasons above, S input, especially atmospheric S deposition, is recognized as a major controlling factor in the production of MeHg.36-39 More recently, however, a shift from atmospheric deposition to agricultural addition was reported as a new influencer of S cycling, and the role of S fertilizers in Hg transformation in agricultural fields was highlighted. 40 In the United States, agricultural S application exceeded ~ 3.3 Tg yr⁻¹ in 2017 (equal to ~ 39.8 kg S ha⁻¹ yr⁻¹),⁴⁰ and this number is projected to increase due to the decline in atmospheric S deposition and resulting S deficiencies in agricultural soils. 41 In China, where SO2 emissions have declined from 21.85 Tg S yr⁻¹ in 2011 to 3.18 Tg S yr⁻¹ in 2021, ⁴² increasing application of S fertilizers has been reported.⁴³ Together, these estimates suggest that agricultural S additions are on par with atmospheric S deposition. Therefore, S-regulated Hg transformation in agricultural fields (e.g., paddy soils) requires more attention. To date, limited studies have examined S input-influenced Hg transformation in paddy soils, with both promotion and inhibition of Hg^{II} methylation reported. 44-47 Most of these studies were based on bulk Hg concentration measurements, with little investigation of the precise transformation processes of Hg. Moreover, S species with different valent states determine the redox cycling of S and, thus, influence Hg transformation.²⁹ Accordingly, the role of different S species in Hg transformation is expected to be differential.

Here, a multi-compound-specific isotope labeling technique was employed together with sulfate and thiosulfate amendments of paddy soil to track Hg methylation, demethylation, oxidation, and reduction, simultaneously. Hg isotope labeling (²⁰⁰Hg^{II}, Me¹⁹⁸Hg, and ²⁰²Hg⁰) and geochemical and microbial approaches were combined to reveal Hg transformation in paddy soils and the underlying biogeochemical mechanisms. In addition to MeHg, isotopic signals of Hg⁰ were determined, providing a more integrated understanding of Hg methylation, demethylation, oxidation, and reduction in paddy soils. In particular, the Hg transformation mechanisms were addressed in this study, especially S-regulated Hg transformation in paddy soils. Knowledge gained from this study can contribute to an improved understanding of Hg biogeochemistry in hydrological fluctuation-regulated ecosystems.

2. MATERIALS AND METHODS

2.1. Sample Collection. Rice paddy soil (surface soil, 1–5 cm) and overlying water samples were collected from three paddy fields. The first was an abandoned Hg mining site (SK, E 109°12′38″, N 27°31′2″) and the second was an artisanal Hg smelting site (GX, E 109°11′30″, N 27°33′50″) in the Wanshan Hg mining area (Wanshan District, Tongren City, Guizhou Province, China). The third was a control site in a rural area close to Guiyang City in Guizhou Province (HX, E 106°31′28″, N 26°25′20″). More detailed descriptions of the

sampling sites are provided in Text S1 in the Supporting Information.

2.2. Preparation of Hg Isotope Tracers. Multicompound-specific Hg isotope tracers, including the inorganic divalent Hg tracer (200 Hg II), methyl-Hg tracer (208 Hg), and elemental Hg tracer (202 Hg 0), were used to trace Hg methylation (i.e., from 200 Hg II to Me 200 Hg and from 202 Hg 0 to Me 202 Hg), MeHg demethylation (i.e., Me 198 Hg losses), Hg reduction (i.e., from 200 Hg II to 200 Hg 0 and from Me 198 Hg to 198 Hg 0), and Hg oxidation/immobilization (i.e., 202 Hg 0 losses). The preparation details are presented in Text S2.

2.3. Incubation Experiment Design. Serum bottles (100 mL, borosilicate glass bottle) were used for the anaerobic incubation experiment in an oxygen-free glovebox (PLAS-LABS, USA). Paddy soil and overlying water were mixed in the glovebox to prepare incubation slurries from each site, as described by Wu et al.²² and Liu et al.²⁵ (see Text S3). Each homogenized slurry (30 mL) was weighed into a serum bottle. The moisture content of the prepared slurries (SK, GX and HX) was around 75% (Text S3). Four treatments, including sulfate (Na₂SO₄) and thiosulfate (Na₂S₂O₃) addition treatments as well as an autoclaved treatment (121 °C for 30 min) and a control treatment, were prepared. The same amount of S (equivalent to 2 mg of S) was added to each of the incubation bottles for the two S treatments. The dosage of exogenous S was similar to the total S content of paddy soils from Wanshan (~200 mg kg⁻¹, ref 48). Isotope-enriched ²⁰⁰Hg^{II}, Me¹⁹⁸Hg, and ²⁰²Hg⁰ tracers were spiked into all incubation bottles; the spiking dosage of Hg tracers depended on the ambient Hg concentration at each site (Table S1). Then, the incubation bottles were immediately sealed and gently shaken to mix the tracers and slurries. They were then covered with aluminum foil. The total period of incubation was 48 h (at 25 °C in the glovebox), and three random bottles (triplicates for each site and each treatment) were destructively sampled at 0 h, 12, 24, and 48 h. However, due to the periods of incubation, bottle preparation, and subsampling, the actual time series for purgeable Hg⁰ was 2, 14, 26, and 50 h, and for MeHg, it was 4, 18, 28, and 52 h (see Text S4.1). After incubation, the isotope-enriched Hg^0 species ($^{198}Hg^0$, $^{200}Hg^0$, and $^{202}Hg^0$), MeHg species ($Me^{198}Hg$, $Me^{200}Hg$, and $Me^{202}Hg$), redox couples $(HS^-/SO_4^{2-}, NO_3^-/NH_4^+, and Fe^{2+}/Fe^{3+})$, and the concentration and optical properties (i.e., UV-vis absorption and fluorescence spectra) of water extracted soil dissolved organic matter (DOM) were determined. Genomic DNA was extracted for the quantification of functional genes that encode Hg and S transformations (hgcA, merA, merB, dsrB, and soxB). Hg-methylating microbial communities were identified by hgcA gene amplicon sequencing and metagenomic analysis, and the sequence data were deposited in the National Centre for Biotechnology Information (NCBI, https://www.ncbi.nlm.nih. gov/), with accession numbers PRJNA950218 and PRJNA950935, respectively. More details on the subsampling and measurements are provided in Text S4. The primers used for quantitative PCR are listed in Table S2.

2.4. Data Analysis. Ambient Hg refers to the Hg that is naturally present in the soil, and isotope-enriched Hg (¹⁹⁸Hg, ²⁰⁰Hg, and ²⁰²Hg) refers to Hg from the spiked tracers. ^{49,50} Mass-bias corrected signals of ambient Hg and Hg tracers were calculated using a simplified approach due to the negligible differences as compared to the matrix-based signal deconvolution approach (Figure S1). Details related to the signal calculation and comparison methods can be found in Text S5.

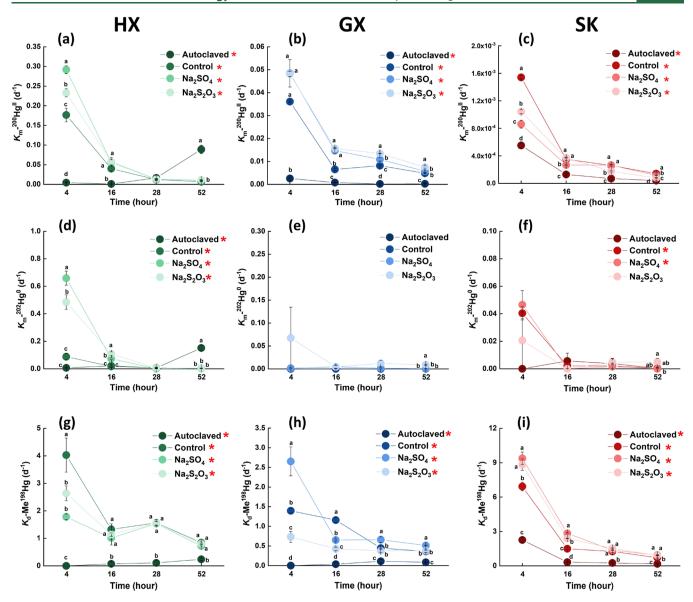

Figure 1. Methylation rate constants for $^{200}\text{Hg}^{2+}$ [K_{m} - $^{200}\text{Hg}^{2+}$, (a-c)], methylation rate constants for $^{202}\text{Hg}^0$ [K_{m} - $^{202}\text{Hg}^0$, (d-f)], and demethylation rate constants for Me¹⁹⁸Hg [K_{d} -Me¹⁹⁸Hg, (g-i)] as a function of time at the three sites (HX, GX, and SK) across the different treatments. Error bars indicate the standard error (\pm SE) for replicates (n = 3). Different lowercase letters indicate that the differences between the treatments at each time point are significant (one-way ANOVA p < 0.05). Missing lowercase letters indicate no significant difference between treatments. "*" after the legend suggests that the differences within each treatment at different times are significant (t-test p < 0.05).

The concentrations of generated MeⁱHg and ⁱHg⁰ (i = 198, 200, and 202) were quantified by external calibrations⁵⁰ (Figure S2). The methylation rate constants $[K_{\rm m}^{-200}{\rm Hg^{II}}~({\rm d^{-1}})$ and $K_{\rm m}^{-202}{\rm Hg}^0$ (d⁻¹)], demethylation rate constant [$K_{\rm d}$ - $Me^{198}Hg$ (d⁻¹)], and volatilization rate constants $[K_v]$ $Me^{198}Hg$ (d^{-1}) and $K_v^{-200}Hg^{II}$ (d^{-1})] were calculated from [MeⁱHg], [i Hg⁰] (i = 198, 200, and 202), and the amounts of spiked Hg tracers using an irreversible pseudo-first-order model.⁵² Meanwhile, the ratios of produced MeHg to spiked inorganic Hg tracers [Me200Hg/200HgII (%) and Me²⁰²Hg/²⁰²Hg⁰ (%)], the ratio of MeHg losses to spiked MeHg tracer [Me¹⁹⁸Hg demethylation (%)], and the ratios of produced purgeable Hg⁰ to spiked Hg tracers [200Hg⁰/200Hg²⁺ (%) and ¹⁹⁸Hg⁰/Me¹⁹⁸Hg (%)] were also obtained. The calculation details and assumptions made for the irreversible pseudo-first-order model are shown in Text S6. It should be noted that linear approximations may underestimate the rate

constants in Hg transformation due to the presence of reversible reactions (e.g., demethylation),⁵³ adsorption, and precipitation of spiked Hg tracers.⁵⁴ Therefore, the rate constants obtained from this study may not be suitable for comparison with other works using different approaches. Similarly, using the measured purgeable Hg⁰ may underestimate Hg^{II} reduction due to the potential existence of nonpurgeable Hg⁰ (e.g., immobilized by solid phases).^{55,56} However, all purgeable Hg⁰ was produced from Hg reduction; therefore, Hg volatilization was used in this study to represent Hg reduction.

2.5. QA/QC and Statistics. The certified reference material (CRM) ERM-CC580 was used, and the MeHg recovery measurement for CRM ranged from 76.2 to 108.4%, with an average of 85.2 \pm 9.07% (n = 26), which is comparable with previous studies. ^{7,16,22,25,46,49} Duplicates were added every 10 samples during measurement, and the relative standard

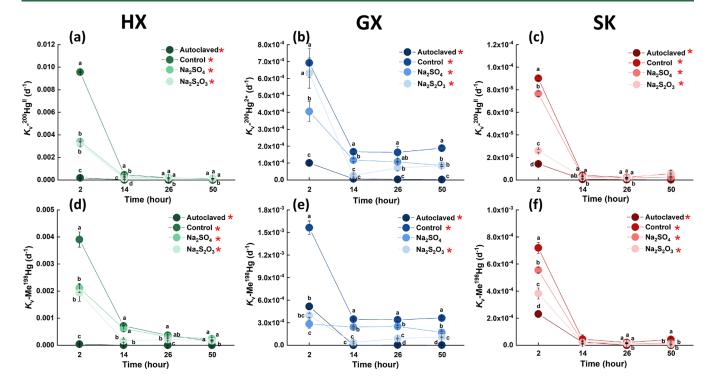

Figure 2. Volatilization rate constants for 200 Hg^{II} [K_{v} - 200 Hg^{II}, (a-c)] and Me¹⁹⁸Hg [K_{v} -Me¹⁹⁸Hg, (d-f)] as a function of time at the three sites (HX, GX, and SK) across the different treatments. Error bars indicate the standard error (\pm SE) for replicates (n = 3). Different lowercase letters indicate that the differences between the treatments at each time point are significant (one-way ANOVA p < 0.05). "*" after the legend indicates that the differences within each treatment at different times are significant (t-test p < 0.05).

deviation (RSD %) of duplicates is <10%. The instrument detection limits for Hg by using inductively coupled plasma—mass spectrometry is 10 pg. Data are presented as the mean \pm standard error (SE). Group differences were assessed by *t*-tests and one-way ANOVA with Duncan's post hoc test using SPSS 23.0 (IBM, IL, USA). Statistical significance (p) was set at <0.05 (two-tailed).

3. RESULTS

3.1. Variations in Major Redox Couples and Soil **DOM.** Redox couples $(HS^--SO_4^{2-}, NH_4^+-NO_3^-, and Fe^{2+}-$ Fe³⁺) were measured to show the redox conditions during incubation. The concentrations of NH₄⁺ in the liquid phases of all paddy slurries were 2-3 orders of magnitude higher than those of NO₃⁻; the highest NO₃⁻ concentrations were observed in the autoclaved treatments (Figure S3). Higher Fe²⁺ percentages in total Fe (Fe²⁺ + Fe³⁺) were found in the two S treatments, as compared to the control treatment, at all sites (p < 0.05, Figure S4). Similar distribution patterns of SO₄²⁻ were found in the Na₂SO₄ and Na₂S₂O₃ treatments at sites HX and SK (Figure S5). The concentrations of sulfide (HS⁻) at all sites were 3 orders of magnitude lower than those of SO₄²⁻ (Figure S5). It is noted that some large variations of $\mathrm{Fe^{2+}}$, $\mathrm{Fe^{3+}}$, and $\mathrm{NO_3}^-$ were observed in the autoclaved samples, and proper explanations are in the Text S7. The concentrations of soil DOM (represented by dissolved organic carbon, DOC) varied across the different sites (p < 0.05, Figure S6) but were similar among the different treatments at a given site (p > 0.05)Figure S6). UV-vis absorption and fluorescence spectra were used to characterize the compositional structure of DOM. Similarly, for almost all spectral indices [i.e., SUVA₂₅₄, S_{275–295}, a(355), fluorescence peaks, HIX, and BIX], there were no differences among the treatments (Figure S7). The only

differences were as follows. First, higher intensities of fluorescence peak A (p < 0.05, Figure S7d) and peak C (p < 0.05, Figure S7e) were observed in the S addition treatments (i.e., both Na₂SO₄ and Na₂S₂O₃ treatments) as compared to the control at site SK. Second, at site GX, lower intensities of fluorescence peak B (p < 0.05, Figure S7f) and peak T (p < 0.05, Figure S7g) were observed in the S addition treatments as compared to the control.

3.2. Copy Numbers of the hgcA, merA, merB, dsrB, and soxB Genes and Hg-Methylating Communities. Copies of the mer operon (merA and merB) were below the detection limit in all treatments at all sites [real-time threshold cycle $(C_T) > 31$]. Significantly lower copies of hgcA, dsrB, and soxB were found in the autoclaved samples compared to the other treatments (p < 0.05, Figure S8). At site GX, the control treatment exhibited more hgcA genes than the two S treatments (p < 0.05, Figure S8b), while the opposite trend was observed at site SK (p < 0.05, Figure S8c). A distribution pattern similar to that of hgcA was found for dsrB at sites GX and SK (Figure S8e,f). More copies of the soxB gene in the Na₂S₂O₃ treatment were observed at the three sites, as compared to those in the Na₂SO₄ treatment (p < 0.05, Figure S8g-i). The hgcA gene amplicon sequencing revealed that the relative abundances of sulfate-reducing bacterium (SRB) methylators (i.e., SRB carrying the hgcA gene) in the S addition treatments at sites HX and GX were 1.04-1.56 and 1.27-1.82 times higher than that in the control, respectively (p > 0.05). The identified major SRB methylators were Peptococcaceae, Desulfovibrionaceae, and Desulfobulbaceae (Figure S9b). The search of the metagenomic data for homologues of hgcA revealed more SRB methylators in the S addition treatments than in the control at site HX (23.5% higher in

sulfate treatment and 17.5% higher in thiolsulfate treatment, Figure S9d).

3.3. Methylation of 200 **Hg**^{II} **and** 202 **Hg**⁰. The methylation rate constants, $K_{\rm m}$ - 200 Hg^{II} (d⁻¹) and $K_{\rm m}$ - 202 Hg⁰ (d⁻¹), show the methylation of spiked 200 Hg^{II} and 202 Hg⁰, respectively (Figure 1). The variation trend in $K_{\rm m}$ - 200 Hg^{II} was the same at all sites, with a sharp decrease from 4 to 16 h and a slight decrease thereafter; the autoclaved treatment at site HX was the only exception. However, the ranges of $K_{\rm m}$ - $^{200}{\rm Hg^{II}}$ among the study sites differed greatly. The highest values of $K_{\rm m}$ - $^{200}{\rm Hg^{II}}$ at sites HX, GX, and SK were all observed at the 4th h, with values of $0.29 \pm 0.01 \text{ d}^{-1}$ (in the Na₂SO₄ treatment, p < 0.05, Figure 1a), $0.048 \pm 0.006 \text{ d}^{-1}$ (in both the Na₂SO₄ and Na₂S₂O₃ treatments, p < 0.05, Figure 1b), and $0.0015 \pm 0.00002 \text{ d}^{-1}$ (in the control treatment, p < 0.05, Figure 1c), respectively. The ratios of produced Me²⁰⁰Hg to spiked ²⁰⁰Hg^{II} [Me²⁰⁰Hg^{II} (%)] and the Me²⁰⁰Hg concentrations during incubation are shown in Figures S10 and S11, respectively. The S treatments yielded more production of $Me^{200}Hg$ than the control treatment at sites HX and GX (p < 10.05, Figure S11), and significantly higher Me²⁰⁰Hg was observed in the Na₂S₂O₃ treatment at site GX than in the Na_2SO_4 treatment (at the 52nd h, p < 0.05, Figure S11b).

The formation of Me²⁰²Hg from spiked ²⁰²Hg⁰ reflects the methylation of ²⁰²Hg⁰. At site HX, the highest $K_{\rm m}$ -²⁰²Hg⁰ was found at the 4th h in the Na₂SO₄ treatment (0.66 \pm 0.05 d⁻¹, p < 0.05), followed by the Na₂S₂O₃ treatment (0.49 \pm 0.05 d⁻¹, p < 0.05) and then the control and autoclaved treatments (p < 0.05, Figure 1a). Correspondingly, 10.98 \pm 0.85 and 8.08 \pm 0.89% of spiked ²⁰²Hg⁰ were transformed to Me²⁰²Hg in the Na₂SO₄ and Na₂S₂O₃ treatments, respectively, at site HX (Figure S10d). At sites GX and SK, more Me²⁰²Hg was produced in the Na₂S₂O₃ treatment than in the other treatments (1.90 \pm 0.17% for GX and 1.07 \pm 0.59% for SK, p < 0.05, Figure S10e,f).

3.4. Demethylation of Me¹⁹⁸Hg. All Me¹⁹⁸Hg tracers yielded significant degradation over time, except in the autoclaved treatments (Figure 1). At site HX, there were no significant differences in K_d -Me¹⁹⁸Hg among the control, Na₂SO₄, and Na₂S₂O₃ treatments across the whole time series, with the exception of K_d -Me¹⁹⁸Hg in the control treatment $(4.03 \pm 0.62 \text{ d}^{-1})$ at the 4th h. At sites GX and SK, the Samended treatments yielded higher K_d-Me¹⁹⁸Hg values than the control treatment at the end of incubation (the Na₂SO₄ treatment in GX and both the Na₂SO₄ and Na₂S₂O₃ treatments in SK) (p < 0.05, Figure 1h,i). Although demethylation of Me¹⁹⁸Hg was also observed in the autoclaved treatments, it was significantly lower than that observed in the other treatments (p < 0.05, Figures S11d-f), suggesting that microbially mediated demethylation of MeHg is predominant in paddy soils.

3.5. Reduction of 200 Hg^{II} and Formation of 198 Hg⁰ from Me¹⁹⁸Hg. The volatilization rate constants, $K_{\rm v}$ - 200 Hg^{II} (d⁻¹) and $K_{\rm v}$ -Me¹⁹⁸Hg (d⁻¹), show the formation of purgeable 200 Hg⁰ and 198 Hg⁰ by the reduction of spiked 200 Hg^{II} and Me¹⁹⁸Hg, respectively (Figure 2). Significantly higher amounts of purgeable 200 Hg⁰ and 198 Hg⁰ were detected in the non-autoclaved treatments than in the autoclaved samples at all sites (Figure S12). However, the ratios of produced purgeable 200 Hg⁰ and 198 Hg⁰ to spiked Hg tracers [200 Hg⁰/ 200 Hg^{II} (%) and 198 Hg⁰/Me¹⁹⁸Hg (%)] were 1–2 orders of magnitude lower than those of Me²⁰⁰Hg/ 200 Hg^{II} (%) and Me¹⁹⁸Hg demethylation (%) (Figures S10 and S13). In the initial period

(2 h), $K_{\rm v}^{-200}{\rm Hg^{II}}$ in the control treatment was higher than those of the S-amended treatments (Na₂SO₄ and Na₂S₂O₃) at all sites (p < 0.05, except $K_{\rm v}^{-200}{\rm Hg^{II}}$ at site GX, Figure 2). Lower purgeable ²⁰⁰Hg⁰ in the S treatments, as compared to the control treatment, was found at site GX across the entire study period (p < 0.05, Figure S12b) and at site HX in the first 14 h of incubation (p < 0.05, Figure S12a).

Similar to K_v^{-200} Hg^{II}, K_v -Me¹⁹⁸Hg in the control treatment at the 2nd h was significantly higher than those of the S treatments at all sites (p < 0.05, Figure 2). However, a comparable purgeable 198Hg0 mass was found between the control and S treatments across most of the incubation period at sites HX and SK (Figure S12d,f). Less purgeable ¹⁹⁸Hg⁰ mass was observed in the Na₂S₂O₃ treatment than the Na₂SO₄ treatment at site GX (p < 0.05, Figure S12e). It should be noted that some production of 198 Hg 0 may be from 198 Hg II reduction instead of from Me¹⁹⁸Hg because the purity of our synthesized Me¹⁹⁸Hg was 83.2%, which means that 16.8% of ¹⁹⁸Hg^{II} remained in the synthesized Me¹⁹⁸Hg. Therefore, the formation of 198Hg⁰ only from Me¹⁹⁸Hg was recalibrated according to the purity of Me¹⁹⁸Hg and the fraction of conversion from ²⁰⁰Hg^{II} to ²⁰⁰Hg⁰ (Text S8). By subtracting ¹⁹⁸Hg⁰ originating from ¹⁹⁸Hg^{II}, we found that 86.4 ± 11.6 , 89.4 ± 10.4 , and $97.1 \pm 3.4\%$ of ¹⁹⁸Hg⁰ were from Me¹⁹⁸Hg at sites HX, GX, and SK, respectively. This confirms the transformation of $Me^{198}Hg$ to $^{198}Hg^0$. Thus, the recalibration procedure is necessary for accurately tracing the reduction of synthesized MeHg tracers; this has been ignored in previous

3.6. Oxidation or Immobilization of 202 Hg 0 . The losses of spiked 202 Hg 0 through purging suggest that purgeable 202 Hg 0 is transformed to non-purgeable 202 Hg. Both oxidation and immobilization are responsible for the formation of non-purgeable 202 Hg. Rapid depletion of purgeable 202 Hg 0 occurred in this study; more than 99.9% of spiked 202 Hg 0 could not be purged out within 2 h (Figure S13g–i). S amendments significantly decreased the masses of purgeable 202 Hg 0 at sites HX and GX when compared with the control treatment (p < 0.05, Figure S12g,h).

4. DISCUSSION

4.1. Mercury Transformation in Paddy Soils. Signals of isotope-enriched Hg tracers in the control and autoclaved treatments showed transformations (i.e., methylation, demethylation, reduction, and oxidation/immobilization) between different Hg species (Hg^{II}, MeHg, and Hg⁰) in paddy soils.

different Hg species (Hg^{II}, MeHg, and Hg⁰) in paddy soils. Significantly lower Me²⁰⁰Hg production (Figures S10 and S11) in the autoclaved treatments compared to the other treatments suggests that abiotic methylation, if present at all, is negligible in paddy soils. Methylation of Hg^{II} ($K_{\rm m}$ -²⁰⁰Hg^{II}) decreased by orders of magnitude over the Hg contamination gradient ([THg]: HX (0.15 \pm 0.003 mg kg⁻¹) < GX (17.2 \pm 1.7 mg kg⁻¹) < SK (609 \pm 7 mg kg⁻¹)), which is consistent with our previous findings. ^{22,25} Microbially mediated processes are likely the cause, ^{22,25} because (i) there were no differences in the soil texture and structure between the sites and (ii) Hg selective pressure can reshape the microbial community structure of paddy soils, altering the abundance of methylators or microbial helpers (e.g., syntrophic microorganisms) that support methylators. ^{57,58} Moreover, a lower concentration but more aromatic DOM (i.e., lower DOC but higher SUVA₂₅₄) was observed at site SK, as compared to sites HX and GX (p <

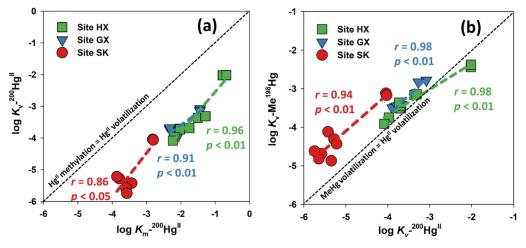

Figure 3. $\log K_{\rm m}^{-200}{\rm Hg^{II}}$ vs $\log K_{\rm v}^{-200}{\rm Hg^{II}}$ (a) and $\log K_{\rm v}^{-200}{\rm Hg^{II}}$ vs $\log K_{\rm v}{\rm -Me^{198}Hg}$ (b) at the three sites (HX, GX, and SK) in the control treatment. Dashed lines represent the 1:1 line between two variables.

0.05, Figures S6 and S7). This implies that DOM with a high humification degree inhibits microbially mediated Hg^{II} methylation. This is also supported by the observed negative correlations between $K_{\rm m}^{-200}{\rm Hg^{II}}$ and the humic-like characters of the DOM at all sites (r=-0.58 and p<0.05 for $K_{\rm m}^{-200}{\rm Hg^{II}}$ vs peak A, r=-0.75 and p<0.01 for $K_{\rm m}^{-200}{\rm Hg^{II}}$ vs peak C, and r=-0.77 and p<0.01 for $K_{\rm m}^{-200}{\rm Hg^{II}}$ vs SUVA₂₅₄, Table S3). Typically, DOM with a lower molecular weight, less humic substances, and more autochthonous sources (e.g., low-molecular-weight organic acids, proteins, and sugars) can more readily fuel microbially mediated Hg^{II} methylation, as compared to highly aromatic or humic substances. 59

Active methylation of ²⁰⁰Hg^{II} (Figures 1a, S10a, and S11a) and increasing copies of the hgcA gene (Figure S8) were observed in the autoclaved treatment at site HX at the end of the period of incubation. This suggests potential microbial succession unaccounted for after autoclaving. An uncertain effect of autoclaving on the inhibition of bacterial activity has previously been reported, which is consistent with this observation.^{22,60} A spread-plate experiment was conducted using autoclaved samples to test the activity of microorganisms (Text S9). No countable colony-forming units were identified, suggesting that the microorganisms responsible for the increase in the hgcA signal in the autoclaved samples are nonculturable with the selected growth medium. Moreover, we observed a significant correlation between methylation using either ²⁰⁰Hg^{II} or ²⁰²Hg⁰ as the substrate in the autoclaved treatment at site HX (Figure S14). This implies that both ²⁰²Hg⁰ and ²⁰⁰Hg^{II} can be methylated and their methylation processes are highly correlated. This is not surprising because Hg⁰ can be methylated after oxidation⁶¹ in cultures of Desulfovibrio desulfuricans ND132^{62,63} and Geobacter sulfurreducens PCA. 63,64 In this study, less than 0.1% of spiked 202Hg⁰ was recovered as purgeable ²⁰²Hg⁰ during incubation (i.e., dominated by non-purgeable ²⁰²Hg, Figure S12g–i). The rapid formation of non-purgeable ²⁰²Hg from spiked ²⁰²Hg⁰ implies the rapid oxidization or solid-phase immobilization of ²⁰²Hg⁰ in paddy soil slurries. Non-purgeable Hg⁰ can be present as Hg⁰ or Hg^{II} associated with particles.⁵⁶ However, with the presence of natural organic matter^{65,66} and some anaerobic bacteria, ^{62,63} Hg⁰ can easily be oxidized to Hg^{II}. In particular, several recent studies have reported that particulatebound HgII can also act as a bioavailable substrate fueling

methylation. ^{67,68} Previously, Colombo et al. ⁶² and Hu et al. ⁶³ reported the biotic oxidation of Hg⁰ through pure culture studies. The current results demonstrated that abiotic reactions likely dominate the oxidization of spiked ²⁰²Hg⁰ due to the lower purgeable ²⁰²Hg⁰ masses recovered from the autoclaved treatments, as compared to the other treatments (p < 0.5, Figure S12g–i). In this study, the spiked ²⁰²Hg⁰ in paddy soils was likely oxidized to ²⁰²Hg^{II} and then microbially methylated. Accordingly, both biotic oxidation ^{61–64} and abiotic oxidation ^{65,66} of Hg⁰ will provide Hg^{II} fuel for methylation. This observation supports the hypothesis that rapid redox recycling of Hg species contributes to Hg speciation resetting, forming bioavailable Hg^{II} at methylation sites. ⁶⁹

In addition to the coupled reactions of oxidization and methylation of Hg⁰ in paddy soils, the reduction of Hg^{II} was also co-varied with the methylation of Hg^{II} , as indicated by the significant correlation between log $K_{\rm m}$ - $^{200}Hg^{II}$ and log $K_{\rm v}$ -²⁰⁰Hg^{II} in the control treatment (Figure 3a). Historically, it was assumed that reduction competes with methylation for bioavailable Hg^{II} substrates; however, this view is rapidly changing, as Hg⁰ has been shown to be capable of serving as a substrate for methylation.^{62,63} In this microcosm study, competition between methylation and reduction was also not observed due to the co-variation between $K_{\rm m}$ -200 Hg^{II} and $K_{\rm v}$ -²⁰⁰Hg^{II} (Figure 3a). Lu et al. ⁷⁰ identified a merA- and merBcontaining iron-reducing bacterium capable of simultaneously methylating HgII and generating Hg0 through reductive demethylation of MeHg in anoxic conditions. Here, no significant correlation was observed between $^{200}{\rm Hg^{II}}$ methylation (shown as $K_{\rm m}$ - $^{200}{\rm Hg^{II}}$ or ${\rm Me^{200}Hg^{I200}Hg^{II}}$ %) and $Me^{198}Hg$ demethylation (shown as K_d -Me¹⁹⁸Hg and Me¹⁹⁸Hg demethylation %), and the merA and merB genes were below the detection limit. This suggests that reductive demethylation of newly formed Me²⁰⁰Hg (via the mer operon) is not the likely mechanism responsible for the correlation between ²⁰⁰Hg^{II} methylation and reduction. Rather, other pathways, such as the involvement of c-type cytochromes in Hg^{II} reduction⁶³ and/or photoheterotrophic or fermentative Hg^{II} reduction,⁷¹ may exist in paddy soils. The former process depends on extracellular electron transfer, whereas the latter depends on the presence of fermentable carbon sources in the dark or stimulation of bacterial phototrophy in the presence of light. 69,71,72 However, the reduction of ²⁰⁰Hg^{II} was 1-2 orders of magnitude lower

than the methylation of ²⁰⁰Hg^{II} (Figures 3a, S11, and S12), suggesting a predominant role of methylation when compared with the reduction of Hg^{II} in paddy soils. It is also possible that the newly produced $^{200}Hg^{0}$ is rapidly re-oxidized to $^{200}Hg^{II}$ prior to being methylated to Me²⁰⁰Hg (i.e., avoiding the purge). This quick redox recycling step may favor 200Hg⁰ accessibility and availability to methylators. As a result, rapid anoxic redox cycling, further away from the air/water interface, may maintain a pool of bioavailable HgII, albeit small, that sustains methylation. Nevertheless, over a large scale or long term, Hg reduction and its subsequent evasion may still contribute to the removal of Hg from rice paddy soils and, therefore, limit the formation of MeHg, especially in uncontaminated paddy soils (i.e., HgII methylation is constrained by the THg concentration). Therefore, it is critical to tease apart the importance of these two pathways for the proper management of paddy systems.

In this study, purgeable ¹⁹⁸Hg⁰ was detected from the spiked Me¹⁹⁸Hg (Figure S12d-f), whereas the ratio of purgeable ¹⁹⁸Hg⁰ to the spiked Me¹⁹⁸Hg (¹⁹⁸Hg⁰/Me¹⁹⁸Hg %) was 3-4 orders of magnitude lower than the Me¹⁹⁸Hg demethylation % (Figures S10 and S13). The copy numbers of the mer operon genes (merA and merB), which mediate reductive demethylawere below the detection limit in the control treatment. In the absence of a broad-range mer operon (i.e., involved in both MeHg degradation and Hg^{II} reduction), merindependent oxidative demethylation (OD) may be a significant mechanism underlying MeHg degradation in paddy soils.⁷⁵ Oxidative demethylation is a nonspecific cometabolic process producing Hg^{II} and CO_2 and is commonly observed in anoxic conditions.^{74,76} In this study, the correlations between K_v -Me¹⁹⁸Hg and K_v -²⁰⁰Hg^{II} (Figure 3b) and between purgeable ¹⁹⁸Hg⁰ and ²⁰⁰Hg⁰ (Figure S15) suggest that the formation of purgeable ¹⁹⁸Hg is a true step reaction. M_o -¹⁹⁸Hg is a true step reaction. M_o -¹⁹⁸Hg is a right size of identity by Me¹⁹⁸Hg is a two-step reaction: Me¹⁹⁸Hg is oxidatively demethylated to ¹⁹⁸Hg^{II} and then reduced to ¹⁹⁸Hg⁰, likely using a pathway similar to ²⁰⁰Hg^{II} reduction. The data points were located close to the log K_v -Me¹⁹⁸Hg: log K_v -²⁰⁰Hg^{II} = 1:1 line (Figure 3b), further supporting the control of Me¹⁹⁸Hg degradation by mechanisms similar to or closely associated with $^{198} Hg^{II}$ reduction. Moreover, significant correlations were observed between the purgeable $^{200} Hg^0$ and $^{202} Hg^0$ masses at all sites (Figure S15), implying that the formation of Hg⁰ from spiked ²⁰⁰Hg^{II}, Me¹⁹⁸Hg, and ²⁰²Hg⁰ tracers is the same as Hg^{II} reduction. This further highlights that the formation of Hg^{II} may be a precondition for subsequent methylation and reduction. In addition, significant correlations between humic-like characters of DOM (i.e., humic-like compounds indicated by peak A and peak C and aromaticity indicated by SUVA₂₅₄) and K_v (i.e., both K_v -Me¹⁹⁸Hg and K_v -²⁰⁰Hg^{II}) were observed but were absent with K_d -Me¹⁹⁸Hg (Table S3). This implies that humic fractions of soil DOM inhibited HgII reduction. This is the major mechanism explaining the inhibited transformation of MeHg to Hg⁰ by humified DOM.

Partitioning of Fe between solid and aqueous phases plays a role in Hg transformation. This was evidenced by the significant correlations between the aqueous Fe concentration (i.e., $Fe^{2+}+Fe^{3+}$) and $K_m^{-200}Hg^{II}$ or $K_v^{-200}Hg^{II}$ in this study (Table S4). Research has demonstrated that reductive dissolution of Fe(oxyhydr)oxides may increase the bioavailability of previously adsorbed Hg^{II} . However, the recrystallization from Fe(oxyhydr)oxides to Fe–S solids (e.g., FeS and FeS₂) may largely decrease the bioavailability of the

released Hg^{II} from Fe(oxyhydr)oxides.^{25,29} The influence of redox cycling of Fe in aqueous phases (Fe²⁺–Fe³⁺ couple) on Hg transformation was absent in this microcosm study. More research on Fe redox cycling in both solid and aqueous phases, and its influence on Hg transformation, is needed in the future.

4.2. Role of Sulfate and Thiosulfate in Hg Transformation in Paddy Slurries. The influences of S addition on Hg methylation/demethylation were not only dependent on the S species but also on the study site (Figures 1 and 2, S11, and S12). The roles of S species in different Hg transformation processes raise two questions: (i) how does the S input influence Hg transformation in paddy soils? and (ii) do sulfate and thiosulfate affect the abovementioned processes to the same extent? These two questions are addressed below.

4.2.1. Hg Speciation Change- vs Microbial-Driven Hg Transformation under S Input Conditions. The bioavailability of Hg and the microbial community are recognized as important factors determining biotic Hg cycling in the natural environment. However, it is still not clear whether S-dependent Hg transformation is regulated by Hg speciation (or mobility/bioavailability) or by changes in the microbial community structure and function in response to S species amendments. Recently, Li et al. 1 and Lei et al. 1 reported that an increase in Hg mobility, rather than changes in the structure and functional profiles of microbial methylators, triggers an enhancement of Hg methylation in S-amended paddy soils. Here, Hg speciation and the microbial community were found to play different roles in Hg methylation in S-treated paddy soils with different Hg contamination levels.

At sites (HX and GX) with low and moderate [THg] levels, opposing influences of S addition on Hg methylation and reduction were observed; the addition of Na₂SO₄ and Na₂S₂O₃ increased the formation of Me²⁰⁰Hg but decreased the formation of 200 Hg 0 from 200 Hg II (p < 0.05, Figures 1, 2, and S10-S13). If the bioavailability of Hg is increased, it is expected that S addition would promote ${}^{\bar{}}\!Hg^{II}$ methylation and reduction synchronously, especially given the presence of the co-varied methylation and reduction of HgII as discussed above (Figure 3a). Despite the very limited experimental evidence, the uptake of Hg^{II} species by Hg methylators and Hg reducers is assumed to be comparable. In our previous study, SRBs were confirmed to be the dominant HgII methylators at site HX and one of the HgII methylators at site GX. 22 Here, both Na2SO4 and $Na_2S_2O_3$ provided SO_4^{2-} , thus fueling the SRB following oxidization or disproportionation of $S_2O_3^{2-78-80}$ Therefore, the SRB-mediated HgII methylation at sites HX and GX was likely promoted. In particular, higher SO₄²⁻ concentrations (p < 0.05, Figure S5a) and copy numbers of the dsrB gene (p <0.05, Figure S8d) in the S treatments compared to the control treatment were identified at site HX. At site GX, however, S addition significantly reduced the abundance of the dsrB gene (p < 0.05, Figure S8e), and this was closely correlated with hgcA gene copies (Figure S16). This implies that in addition to SRB, other microorganisms are also involved in HgII methylation, and SO_4^{2-} might be a limiting factor for methylation at site GX.²² In addition, more SRB methylators were observed in the S addition treatments compared to the control at sites HX and GX through either hgcA gene amplicon sequencing or metagenomic analysis (Figure S9), which provides direct evidence that the activity of SRB methylators was promoted by adding both sulfate and thiolsulfate. Among all the identified SRB methylators, Desulfomonile is likely a key SRB genus associate with HgII methylation at sites HX and GX

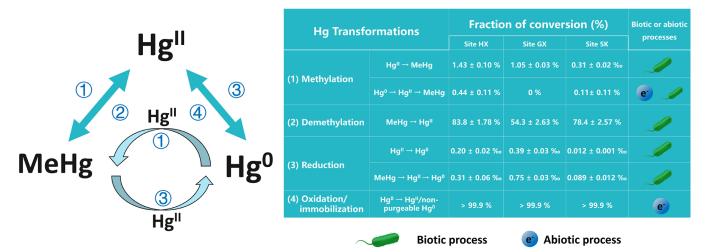

Figure 4. Schematic diagram illustrating Hg cycling in paddy soils and transformation rates of each process. Fractions of conversion are from Figures S10 and S13.

under S addition, due to its significant co-variation with log $K_{\rm m}$ -²⁰⁰Hg^{II} (Figure S17).

Inhibition of 200 Hg^{II} reduction under S addition at sites HX and GX (p < 0.05, Figures 2 and S12) could be interpreted in two ways. (i) S addition promotes both Hg^{II} and Hg⁰ methylation. The rapid redox cycling of Hg⁰ makes it a bioavailable substrate for methylation (discussed above) which, therefore, reduces the amount of purgeable Hg⁰. (ii) Exogenous S addition may break the balance between Hg^{II} methylators (i.e., SRB) and Hg^{II} reducers, thereby reducing the activity of Hg^{II} reducers. However, the communities of Hg^{II} reducers in this study remain unknown (i.e., *merA*-independent reducers), and more research is needed.

At the most contaminated site (SK, with the highest [THg]), Hg^{II} methylation and reduction were hampered, whereas demethylation of MeHg was promoted in the Streated paddy soils when compared with the control treatment at site SK (Figures 1, 2, S11, and S12). It should be noted that a much higher NO₃⁻ concentration (1–3 orders of magnitude higher than those at sites HX and GX) was observed in the autoclaved treatment compared to the other treatments at site SK (p < 0.05, Figure S1c). This suggests that significant dissimilatory reduction of NO₃⁻ occurred in the presence of microorganisms.⁸¹ The reduction of a large amount of NO₃⁻ may deplete electron donors for HgII methylation (e.g., sulfate reduction, iron reduction, and methanogenesis processes) and Hg^{II} reduction, $^{82-84}$ as evidenced by the higher SO $_4^{2-}$ (p <0.05, Figure S5) and lower Fe²⁺ (p < 0.05, Figure S6) concentrations at the end of incubation when compared with sites HX and GX. In addition, our previous work revealed that methanogens are involved in MeHg formation at site SK.²² In this study, among the community of Hg methylators, higher relative abundances of Methanothrix and Methanoregula, carrying hgcA genes, were observed at site SK as compared to sites HX and GX (Figure S9c). Therefore, adding SO_4^{2-} will bring more competition for substrates between SRB and methanogens. In particular, the formation of CH4 is thermodynamically more difficult than the reduction of SO₄²⁻ (i.e., a lower Eh is required).⁸⁵ In the matter of MeHg demethylation, promotion of SRB by the addition of SO₄²⁻ sources may facilitate SRB-mediated OD, since SRB is one of the major players in OD, ^{74,86} and OD was the dominant pathway for MeHg degradation in this study. The role of DOM

in Hg transformation among different treatments is limited, due to the comparable optical properties for most of the indices (Figure S6). It is worth mentioning that consumption of protein-like compounds under the S addition treatments was observed at site GX (lower peak B and peak T than control, p < 0.05, Figure S6e,f). This partly explains the promoted activity of microorganisms (e.g., SRB) under sulfate and thiosulfate addition because the protein-like substances could be utilized preferentially by microorganisms.

The evidence discussed above suggests that the increased production of MeHg is likely attributed to the facilitated activity of Hg^{II} methylators under the exogenous S input. Hg transformations are more sensitive to microorganisms involved in S cycling than Hg speciation changes regulated by reduced S species. S amendments affect the microbial community structure and functional profile of Hg methylators by directly supplying metabolic substrates (i.e., SO₄²⁻ for SRB) or amplifying the competition for metabolic substrates.

4.2.2. Sulfate vs Thiosulfate. Sulfate is a terminal electron acceptor, and thiosulfate is one of the major intermediates in S redox cycling. 78,80,88,89 In this study, the rates and magnitudes of Hg transformations in the S treatments were dependent on the S species (i.e., SO_4^{2-} and $S_2O_3^{2-}$).

Previous studies have reported that HgII can bind with $S_2O_3^{\ 2-}$ and form bioavailable $Hg-S_2O_3$ complexes [e.g., $Hg(S_2O_3)_2^{\ 2-}$ and $Hg(S_2O_3)_3^{\ 4-}],^{90-93}$ which may be the mechanism underlying Na₂S₂O₃ addition-promoted methylation. However, the current results appear to suggest a different scenario. We suspect that the added S₂O₃²⁻ was unstable and readily transformed into SO_4^{2-} rather than forming Hg-S₂O₃ complexes; this is evidenced by the similar SO₄²⁻ concentrations to those in the Na₂SO₄ treatment (Figure S5a-c). Furthermore, our modeling exercise (Visual MINTEQ, Text S10) predicted that the speciation of HgII was dominated by Hg-sulfide complexes [e.g., HgS₂H⁻, Hg(SH)₂⁰, and HgS₂²⁻, Figure S18]; Hg-S₂O₃ complexes, if present at all, were negligible when sulfides were present in the paddy soils. In addition to Hg speciation changes, the prolonged supply of SO₄²⁻ to Hg^{II} methylators in the Na₂S₂O₃ treatment is probably another mechanism for the enhanced Hg^{II} methylation. Rapid depletion of $SO_4^{\ 2-}$ was found in the Na_2SO_4 treatment. However, in the Na₂S₂O₃ treatment, S₂O₃²⁻ and its acid decomposition products (i.e., SO_3^{2-} and S^0)⁷⁹ involved in

disproportionation also continuously supplied SO₄²⁻. These reactions are considered to be typical inorganic fermentations and are independent of external reductants or oxidants.⁹⁴ In the current study, the formation of $SO_4^{\ 2-}$ at site GX was slower than at sites HX and SK, suggesting that the oxidation of $S_2O_3^{2-}$ was likely concomitant with the reduction of SO_4^{2-} in the Na₂S₂O₃ and Na₂SO₄ treatments, respectively (Figure S5b). Moreover, higher abundances of S-oxidizing bacteria (soxB gene) were observed in the $Na_2S_2O_3$ treatments than the Na₂SO₄ treatments. In particular, copies of the soxB gene were negatively correlated with [HS $^-$] at site GX (r = -0.87 and p <0.01), which further confirms the capability of $S_2O_3^{2-}$ to replenish SO_4^{2-} through S oxidation (Figure S8g-i). This highlights that the role of S-oxidizing bacteria in SRB-mediated Hg methylation should be given more attention. In summary, the mechanisms of S₂O₃²⁻- and SO₄²⁻-regulated Hg methylation are partly different. Both can enhance SO_4^2 supply for HgII methylation, albeit at different rates. Therefore, the kinetics of SO_4^{2-} production or microbial SO_4^{2-} utilization influenced by the $S_2O_3^{2-}$ input can more likely explain the greater formation of MeHg in the Na₂S₂O₃ treatment. This deserves further study in the future. Although this study was not able to provide evidence as to how Hg speciation changes influence Hg methylation under S addition, this should not be ignored, especially in redox-fluctuation paddy soils.

5. ENVIRONMENTAL IMPLICATIONS

In addition to the widely accepted Hg^{II} methylation and MeHg demethylation, this study provides direct evidence of HgI reduction, Hg⁰ oxidation/immobilization, Hg⁰ methylation, and the formation of Hg⁰ from MeHg in paddy soils (Figure 4). These processes are biotically mediated, with only one exception being that Hg⁰ oxidation/immobilization is mainly mediated by abiotic processes. The finding that dark reduction of HgII occurs through a biotically mediated process in paddy soils further highlights the role of microbial reduction of Hg^{II} in this environmental media. Interestingly, Hg⁰ from the dark reduction of Hg^{II} can be methylated upon re-oxidation. The comparable $K_{\rm m}^{-202}Hg^0$ and $K_{\rm m}^{-200}Hg^{II}$ values further imply the rapid redox recycling of Hg species, fueling methylation. The transformation of MeHg to Hg⁰ is attributed to oxidative demethylation coupled with reduction, instead of reductive demethylation (RD), in flooded paddy soils; RD may occur during the drying period (air-exposed) of rice-growing in paddy soils.⁷⁴ These findings highlight that (i) biotically mediated dark reduction of Hg^{II} followed by re-oxidation is also a source of HgII methylation in flooded paddy soils; this has been largely overlooked previously in redox fluctuating environments; and (ii) transformation processes for different Hg species (Hg⁰, Hg^{II}, and MeHg) in paddy soils are closely associated with each other. In addition to HgII reduction and methylation as mentioned above, MeHg may also be a source of Hg⁰ emission into the atmosphere through oxidative demethylation and then reduction. This highlights the continuous and dynamic nature of Hg transformation in paddy soils.

Sulfate reduction and the formation of reduced S species (sulfide, elemental sulfur, polysulfides, etc.) have long been considered as factors influencing Hg transformation due to the role of the SRB in Hg^{II} methylation^{38,89} and speciation changes of Hg.^{29–31} However, this study implies that the oxidation of reduced S species by S-oxidizing bacteria is also an important process in Hg^{II} methylation. The likely mechanisms are (i) to

provide more sulfate and (ii) to change the rate of sulfate supply in sulfate reduction. Therefore, SRB-mediated Hg^{II} methylation is not only influenced by the quantity of sulfate but also controlled by the kinetics of sulfur species transformations, warranting additional work to fully explore their connection to Hg methylation.
