ABSTRACT

Study objective To evaluate the competency of trained health workers in detecting and managing hypertensive disorders of pregnancy during routine antenatal check-ups (ANCs) at primary care facilities in Bangladesh.

Study design and settings Cross-sectional study; conducted in 26 primary care facilities.

Outcome measures Accurate diagnosis of the hypertensive disorders of pregnancy.

Method In total 1560 ANC consultations provided by primary health workers, known as Family Welfare Visitors (FWVs), were observed using a structured checklist between October 2017 and February 2018. All consultations were reassessed by study physicians for validation.

Result Of the 'true' cases of gestational hypertension (n=32), pre-eclampsia (n=29) and severe pre-eclampsia (n=16), only 3%, 7% and 25%, respectively, were correctly diagnosed by FWVs. Per cent agreement for the diagnosed cases of any hypertensive disorders of pregnancy was 9% and kappa statistics was 0.50 (p value 0.0125). For identification of any hypertensive disorders by FWVs, sensitivity and positive predictive values were 14% and 50%, respectively. There was a moderate positive correlation between the blood pressure measurements taken by FWVs and study physicians. Only 27% of those who had 'some protein' in urine were correctly identified by FWVs. Women diagnosed with any of the hypertensive disorders of pregnancy by FWVs were more likely to be counselled on at least one danger sign of pre-eclampsia (severe headache, blurring of vision and upper abdominal pain) than those without any such diagnosis (41% vs 19%, p value 0.008). All four cases of severe pre-eclampsia diagnosed by FWVs were given a loading dose of intramuscular magnesium sulphate and three among them were referred to a higher facility.

Conclusion The FWVs should be appropriately trained on risk assessment of pregnant women with particular

Strengths and limitations of this study

- The study used a direct-observation based approach to evaluate the competency of health workers in diagnosing and managing hypertensive disorders of pregnancy during antenatal check-ups and also validated the accuracy of the performed activities (blood pressure (BP) measurement and urinalysis).
- Post-hoc analysis based on the two diagnostic criteria, elevated BP and protein in the urine as per the national guideline, indicates the percentage of 'true' cases of hypertensive disorders of pregnancy accurately diagnosed to be markedly increased.
- The study assessed the competency of health workers in primary care facilities of rural areas in Bangladesh, therefore, the findings are not generalisable to health workers working in the higher level of health facilities.
- The study could not determine the extent to which the deviations of measurements from the 'true' values were attributed to the error of the instruments (BP machine or urine test kits) since the instruments used by the health workers were not validated.
- Hawthorn effect was possible by the presence of observers and study physicians, however, their continual presence over 2 weeks in the selected facilities could potentially minimise the effect.

emphasis on accurately assessing the diagnostic criteria of hypertensive disorders of pregnancy and its management.

INTRODUCTION

Pre-eclampsia, a multisystem hypertensive disorder of pregnancy, is associated with high blood pressure (BP; diastolic BP >90 mm Hg)

and the presence of protein in urine.¹ The risks of adverse maternal and perinatal health outcomes are high when an advanced form of pre-eclampsia develops and leads to episodes of convulsion—a condition known as eclampsia. Eclampsia may lead to serious maternal health consequences including renal failure² and placental abruption³ and accounts for 10% of maternal deaths worldwide.^{4 5} Despite the substantial reduction of maternal mortality ratio over the past decade in Bangladesh,⁶ eclampsia remains the second major direct cause of obstetric deaths constituting about 20% of all maternal mortalities.⁷ The condition is also associated with adverse fetal outcomes such as stillbirth, preterm delivery and intrauterine growth restriction.⁸

The key strategy to mitigate the burden related to pre-eclampsia is to diagnose the condition early so that timely and appropriate management can prevent further complications.⁹ The provision of injectable magnesium sulphate as the first stage management of severe pre-eclampsia can prevent the severity of its progression and lowers the risk of convulsion.¹⁰ The availability of life-saving interventions alone, however, does not ensure its delivery to the beneficiaries without improving the overall service provision for maternity care by skilled health workers.¹¹ Some studies reported poor quality of antenatal check-up (ANC) regarding the detection and management of pre-eclampsia and observed incomplete physical examinations by the ANC providers.^{12 13} Lack of accuracy in BP measurement and urinary protein assessment can further compromise the detection of hypertensive disorders, including pre-eclampsia during pregnancy. There is, however, a scarcity of evidence on the accuracy of the clinical examinations conducted by the ANC providers.

In Bangladesh, female primary level health workers, known as Family Welfare Visitors (FWVs) with 18 months of preservice training, provide ANC services at community level primary healthcare centres (known as union health and family welfare centre or UH&FWC) and community outreach centres (known as satellite clinics).¹⁴ The FWVs are designated to identify, manage and refer pre-eclampsia cases, and provide initial management of severe pre-eclampsia before referring the pregnant women to health facilities for comprehensive emergency obstetric care (CEmOC).¹⁵ It is, therefore, crucial to accurately perform the essential components of ANC by the FWVs for accurate screening, diagnosis and subsequent management of pre-eclampsia or severe pre-eclampsia.¹⁶ The essential components of ANC include taking an appropriate history, measuring BP, assessing urinary protein and applying the appropriate clinical guidelines.¹⁷

The study objective is to evaluate the competency of FWVs in diagnosing and managing hypertensive disorders of pregnancy including gestational hypertension, pre-eclampsia, severe pre-eclampsia and eclampsia. The study also validated the BP measurement and urinary protein assessment conducted by FWVs by comparing the values with those assessed by study physicians (gold standard). This study was conducted during the provision of

routine antenatal services by the FWVs at the UH&FWCs and satellite clinics in Bangladesh.

The study will identify the quality gaps and the missed opportunities for the detection and management of hypertensive disorders in pregnancy during the ANC in primary care settings in Bangladesh. The findings will guide the maternal health programmers and policy-makers to design effective interventions for improving the accuracy of antenatal screening for hypertensive disorders of pregnancy and reinforce the implementation of the national screening and management protocols for pre-eclampsia and eclampsia.

METHODOLOGY

Study design

We conducted a cross-sectional study at UH&FWCs and satellite clinics, two important primary healthcare service delivery platforms for mothers and children in Bangladesh. UH&FWCs are situated at the lowest administrative units (union) of the country and governed by the Directorate General of Family Planning of Ministry of Health and Family Welfare in Bangladesh and serve a population of 24 000–30 000 on average.¹⁴ In each UH&FWC, one female health worker, known as 'FWV', is posted to provide antenatal, childbirth and postnatal care, and family planning services 6 days a week. In addition to the regular UH&FWC-based services, FWVs conduct outreach sessions that is, attend satellite clinics on two selected days every week. These sessions are usually held in a preidentified household of the village, a school premise, or a community clinic so that FWVs can provide the standard antenatal care and family planning services close to the community. The FWVs carry the required logistics for antenatal care to the satellite clinics, such as registers, job aids and counselling materials, BP machines with the stethoscope, urine test kits, weighing machine and essential medicines to provide standard ANC services.

Methods of data collection included—(i) observation of ANC services provided by FWVs by trained paramedics and (ii) reassessment of the pregnant women by trained physicians which was considered the *gold standard* for validating the FWV's assessment.

Study site

We conducted the study in 26 UH&FWCs selected purposively from four subdistricts of three districts (Habiganj, Noakhali and Lakshmipur) in Bangladesh. In these three districts, The United States Agency for International Development (USAID) funded MaMoni Health Systems Strengthening (MaMoni HSS) project provided technical support to effectively implement the management of hypertensive disorders of pregnancy through existing government health workers.¹⁸ The project trained the FWVs in the selected UH&FWCs on detection, prevention and management of hypertensive disorders of pregnancy using the loading dose of intramuscular magnesium sulphate according to the standard protocol between

March and May of 2016. The 2-day long training was conducted by expert consultants following the CEmOC training manual developed by the Obstetric and Gynaecological Society of Bangladesh. MaMoni HSS also ensured the availability of injectable magnesium sulphate and 'urine strip' for urine assessment in government health facilities including UH&FWC, subdistrict and district hospitals through a strong liaison with the government in these districts. The project also introduced referral slips to ensure that the identified severe pre-eclampsia or eclampsia cases at the UH&FWCs could be referred to the designated CEmOC health facilities of the respective districts for further management. The project also provided infrastructural and skill improvement inputs to improve the quality of CEmOC services at the referral facilities. MaMoni HSS's inputs at different levels for implementing appropriate detection and management of pre-eclampsia and eclampsia at antenatal care contact points of the public facilities have been described elsewhere in detail.¹⁸

Data collection

We recruited six female paramedics with 4 years of training by government authorised 'Medical Assistant Training School' and three physicians for the study. After recruitment, the paramedics and the physicians received a 3-day training on ANC and hypertensive disorders of pregnancy using the national protocol for detection and management of pre-eclampsia and eclampsia. Following the training, both study paramedics and physicians participated in a demonstration on the usage of BP machine and urine assessment kit for standardisation in the steps of assessment and recording the result. Before starting the actual data collection, the assessors spent 2 days in a government training hospital for practising the assessment tools, BP machine and urine test kits.

Study paramedics stayed in the ANC consultation room and collected observation-based data when the FWV provided the ANC services. They observed ANC service provided by the FWVs both at UH&FWCs and satellite clinics using a structured observation checklist. The checklist was developed from the components of the WHO focused ANC guideline and incorporated the detail of steps for diagnosing and managing hypertensive disorders of pregnancy.^{17 19} The observers recorded whether the health worker asked about the relevant history of current and previous pregnancy (if any), performed routine examinations such as measuring BP and assessing urine for protein and made a diagnosis for any of the four hypertensive disorders of pregnancy—gestational hypertension, pre-eclampsia, severe pre-eclampsia and eclampsia. The observers also recorded the diastolic and systolic BP, and the findings from urine assessment as measured by the FWVs in the checklist. If the FWVs provided the first dose (ie, the loading dose) of injectable magnesium sulphate to a diagnosed case of severe pre-eclampsia and eclampsia as per the protocol and/or referred the pregnant woman to CEmOC equipped

health facilities, it was also recorded in the checklist. They also extracted the obstetric and background information of the pregnant women from the FWV's ANC registers.

After completion of ANC service provision by the FWV, gold-standard study physicians reassessed every pregnant woman for the symptoms of hypertensive disorders of pregnancy following the standard national protocol. The study physicians measured the diastolic and systolic BP and tested urine for the presence of protein and recorded the information in a structured form. Study physicians conducted the reassessments in a space with auditory and visual privacy and separate from the routine ANC consultation room so that the reassessment activities were less likely to bias the routine practices of FWVs. The physicians independently applied the national protocol to identify the presence of any of the four conditions of hypertensive disorders. To avoid bias during the reassessment of a woman, the study physicians were unaware of any diagnosis or management provided by the FWVs before the reassessment. For example, where an FWV managed a diagnosed case of pre-eclampsia or severe pre-eclampsia by administering the first dose of injectable magnesium sulphate, the study physicians still reassessed the woman. In another situation, where an FWV missed the diagnosis of hypertensive disorders of pregnancy but the case was identified by the study physician, on ethical grounds, the woman was sent back to the FWV with a suggestion from the study physician to re-evaluate the woman. According to the ethical principles, once these women were diagnosed with hypertensive disorders of pregnancy by physicians (gold-standard) and were referred to a re-evaluation by FWV, it was guaranteed that these women received appropriate management and followed the instructions given by the FWV.

Between October 2017 and February 2018, we conducted observation and reassessment of a total of 1560 ANC consultations, 955 in UH&FWCs and 605 in satellite clinics. The study physicians also assessed the readiness status of the 26 selected UH&FWCs for screening and managing hypertensive disorders of pregnancy using a structured health facility assessment checklist. The checklist included information on maternal service availability, human resources, availability of magnesium sulphate, urine strip, functional BP machine and other required logistics. This checklist was adapted from an evaluation survey exploring the quality of antenatal care in government health facilities of Bangladesh.²⁰

Data quality assurance and management

Several data quality checks were in place to correctly record and perform the assigned tasks by the data collectors. The most critical element of the study was the ascertainment of systolic and diastolic BP and protein in urine during reassessment. To measure the BP, manually inflated aneroid sphygmomanometers were used by the study physicians as this instrument was routinely used by the FWVs in UH&FWCs. This type of sphygmomanometer is more portable and preferable for community-level

health services than any other BP measuring devices, though considered less accurate than a mercury sphygmomanometer.^{21 22} To minimise the variation in measurements during reassessment, BP was measured two times for each ANC recipient in the same hand (right arm, unless there was any clinical or physical condition), on a sitting position, and at 5 min of resting interval between two measurements. Both measurements were recorded during the reassessment by the study physicians and the average of these two measurements was used in the statistical analysis. The standard procedures were also maintained during the ‘Non-Communicable Disease Risk Factor Survey Bangladesh 2010’²³ and suggested in the ‘WHO STEPS guideline’.²⁴ For urine reassessment, a sample of urine was collected in a test tube maintaining adequate sterility and hygiene. Reagent strips for urine analysis were used to assess the presence of protein in the sample. The same test-strips were also being used in the selected UH&FWCs for ANC services as supplied by the government with support from MaMoni HSS.

Study paramedics reviewed each other’s ANC observation checklist for completeness before submitting it to the study physician of the team who rechecked each form for missing information or inconsistency. Throughout the study period, one medical officer of the central research team conducted spot-checking that is, made unscheduled visits to study sites, reviewed the collected data on the spot and provided necessary feedback to the study physicians and the paramedics. Regular monitoring and supervision were conducted by the central team of research investigators led by the principal investigator of the study.

A central data management team was responsible for data entry, consistency checking and cleaning. All data were entered into the database using a custom-designed

data entry programme with built-in range and consistency checks.

Definition of variables and data analysis

Four conditions, namely gestational hypertension, pre-eclampsia, severe pre-eclampsia and eclampsia were collectively considered the hypertensive disorders of pregnancy in this study, and their operational definitions are summarised in [table 1](#). The diagnostic criteria mentioned in the operational definitions followed the nationally adapted protocol for the detection and management of hypertensive disorders of pregnancy (online supplemental file 1). The study physicians reassessed each ANC recipient, performed the required examinations and applied the diagnostic criteria based on their assessment to reach a diagnosis. For the FWVs, on the other hand, if they made a diagnosis of one of the four hypertensive disorders of pregnancy and recorded it on the ANC register or the ANC card of the recipient, it was considered as the ‘case detected by FWV’ irrespective of the validity of their assessment for such conditions. In case the FWVs did not record or document any diagnosis for a pregnant woman, the diagnosis was considered as ‘no hypertensive disorder of pregnancy’.

Descriptive statistics were used to report the background characteristics of the ANC recipients; competency of the FWVs in screening, detection and management of hypertensive disorders of pregnancy and presented in percentage of cases who received health services (exploring clinical symptoms, performing screening procedures, counselling, providing injectable magnesium sulphate and referral) in adherence to the standard ANC guideline. The background characteristics of the ANC recipients and the findings on screening procedures were

Table 1 Operational definitions of hypertensive disorders of pregnancy

Hypertensive disorders of pregnancy	Diagnostic criteria
Gestational hypertension	<ul style="list-style-type: none"> ▶ Gestational age: 20 weeks or more. ▶ Diastolic blood pressure: 90–109 mm Hg. ▶ Protein in urine: nil. ▶ Absence of all three danger signs—severe headache, blurred vision and upper abdominal pain.
Pre-eclampsia	<ul style="list-style-type: none"> ▶ Gestational age: 20 weeks or more. ▶ Diastolic blood pressure: 90–109 mm Hg. ▶ Protein in urine: present. ▶ Absence of all three danger signs—severe headache, blurred vision and upper abdominal pain.
Severe pre-eclampsia	<p>Definition#1:</p> <ul style="list-style-type: none"> ▶ Gestational age: 20 weeks or more. ▶ Diastolic blood pressure 90–109 mm Hg. ▶ Protein in urine: present. ▶ Presence of at least one of the three danger signs—severe headache, blurred vision and upper abdominal pain. <p>Definition#2:</p> <ul style="list-style-type: none"> ▶ Gestational age: 20 weeks or more. ▶ Diastolic blood pressure: 110 mm Hg or more. ▶ Protein in urine: present.
Eclampsia	<ul style="list-style-type: none"> ▶ Gestational age: 20 weeks or more. ▶ Diastolic blood pressure: 90 mm Hg or more. ▶ Convulsion.

further stratified by place of service delivery—UH&FWC and satellite clinics. Pearson's χ^2 test was conducted to assess whether participants' characteristics were significantly different between UH&FWC and satellite clinics and assess the significance of the association between the FWV's practice and place of service delivery.

Inter-rater agreement between FWV and study physician was measured using per cent agreement. Cohen's kappa coefficient along with the p value was also estimated to account for the possibility of finding the agreement by chance. Cohen's kappa coefficient describes the strength of inter-rater agreement by comparing the observed agreement to the expected agreement, assuming the measurements are independent.²⁵ Sensitivity, specificity and positive predictive values (PPVs) were calculated for assessing the validity of FWV's diagnosis of—(i) any hypertensive disorder of pregnancy (including gestational hypertension) and (ii) pre-eclampsia, severe pre-eclampsia or eclampsia. For sensitivity and specificity analysis of the conditions (i) and (ii), the measurements and diagnosis made by the study physicians were considered as 'true' or 'gold standard'. Sensitivity was expressed as the percentage of 'cases detected by FWV' among those who had 'true' medical criteria for hypertensive disorders of pregnancy, specificity was expressed as the percentage of non-cases detected by FWV among those who did not have 'true' medical criteria for those conditions, and the PPV was expressed as the percentage of 'true' cases among the 'case detected by FWV' as hypertensive disorders of pregnancy. As part of the validity analysis, two scenarios were compared with the study physician's diagnosis (gold-standard)—(i) diagnosis that was made by FWV and recorded in the ANC registers/ANC card irrespective of using the algorithm present in the national protocol for detecting hypertensive disorders of pregnancy and (ii) post-hoc diagnosis using the information from FWV's measurement of BP and urine assessment, the status of danger signs from study physician's assessment and applying the algorithm during analysis. The latter indicates the extent to which cases could have been accurately diagnosed had the two diagnostic criteria (elevated BP and protein in the urine) been appropriately used as per the national protocol for hypertensive disorders of pregnancy by FWVs.

Pearson's correlation coefficient was reported along with p values to estimate the relationship between the measurements taken by the FWV and the study physician. The comparison is presented in scatterplot graphs by plotting BP recordings taken by FWVs against those taken by study physicians. Mean and SD of absolute difference of BP readings taken by FWVs and study physicians are calculated to estimate the accuracy of FWV's measurement of diastolic and systolic BP. A first-order polynomial smooth curve of the absolute differences is also fitted in the scatter plot to show the deviation from the 'true' values. Accuracy of urine assessment is presented in the percentage of cases where FWV could correctly identify if there was 'no protein' or 'some protein' in the

urine. The results of the urine assessment ascertained by study physicians were considered 'correct'. We used the Strengthening the Reporting of Observational Studies in Epidemiology cross-sectional checklist when writing this manuscript.²⁶

Patient and public involvement

The study objectives and outcome measures were related to assessing the competency of health workers in detecting and managing gestational hypertension, pre-eclampsia, severe pre-eclampsia and eclampsia during ANCs in primary care health facilities in Bangladesh. Pregnant women were not involved in the design of, in the recruitment to and conduct of the study. The results will be disseminated among the health managers and maternal health workers in the government hospitals where the study was conducted.

This study was not a clinical investigation. MaMoni HSS project only provided technical support for the implementation of the nationally adopted intervention of community-based provision of the loading dose of magnesium sulphate to the identified cases of severe pre-eclampsia and eclampsia through the government health system. Nonetheless, systematic reviews and the efficacy trials of magnesium sulphate have already proven that the drug is safe with no major side effects.^{27–29}

RESULT

Readiness of UH&FWCs

All 26 UH&FWCs provided antenatal services and the mean (\pm SD) number of ANC provided in a month was 111 (\pm 83) (data not presented in table). All the UH&FWCs had one designated FWV who provided ANC, childbirth, postnatal care and family planning services. She also conducted regular satellite sessions two times a week to provide the same health services in the satellite clinics. All 26 FWVs received hands-on training on screening, diagnosing and managing hypertensive disorders of pregnancy. In only seven UH&FWCs (27%), at least one case of diagnosing and managing pre-eclampsia in the last 3 months preceding the assessment was reported. The BP machines and urine strips for assessing protein in urine were available in all 26 health facilities, but three did not have injectable magnesium sulphate available during the assessment period. The standard national guideline for managing hypertensive disorders during ANC was available in only 16 out of 26 facilities. The readiness of the satellite clinics regarding the service provision and logistics remained similar to that in the UH&FWC since the FWV carried the ANC logistics with her while attending the satellite sessions.

Characteristics of pregnant women and information on ANC care-seeking

Of the 1560 pregnant women, 955 (61%) received ANC at UH&FWCs and the rest at satellite clinics (table 2). About 69% of women were aged between 20 and 29 years

Table 2 Characteristics of pregnant women and information on ANC care-seeking

Characteristics, N=1560	All, %	UH&FWC, %	SC, %	P value*
Total pregnant women, n	1560	955	605

ANC, antenatal check-up; SC, satellite clinic; UH&FWC, union health and family welfare centre.

and 38% were first-time mothers (primigravida). One in five women came for ANC after 20 weeks of gestational age; among them, 40% came for the first antenatal visit. The gestational age and the order of the ANC visits of the participants were significantly different between those who received care at UH&FWCs and satellite clinics.

Screening and assessment by FWV for hypertensive disorders of pregnancy during ANC

During antenatal service provision, FWVs asked only 8% of women whether they had a history of hypertension or taking any antihypertensive drug or of pre-eclampsia (if the women had previous pregnancy) (table 3). Symptoms of pre-eclampsia for the current pregnancy such as severe headache, blurring of vision, upper abdominal pain, were assessed among 15%, 12% and 18% of women, respectively. Only for 12% of women, any occurrence of convulsion during their current pregnancy was explored. FWVs were more likely to ask these screening questions if the services were given at a UH&FWC than in a satellite clinic ($p<0.05$). BP and urine assessment, two critical examinations for diagnosing the presence and severity of hypertensive disorders of pregnancy, were conducted among 97% and 76% of the women, respectively.

Accuracy of FWV's assessment of BP and urine

BP measurement

Figures 1 and 2 plot the diastolic and systolic BPs of pregnant women, respectively, as recorded by the FWVs against those recorded by the study physicians. Both figures show a tendency of FWVs to round off the BPs to the nearest tenth of the unit which either underestimated or over-estimated the 'true' values as evident by comparing with the study physicians' measurements. The correlation coefficients of the measurements taken by FWV and the study physician were 0.50 (p value <0.0001) for diastolic pressure and 0.60 (p value <0.0001) for systolic pressure, which indicates a significant moderate positive relationship. Overall, the mean (\pm SD) absolute difference between FWV and the study physician's measurement of diastolic and systolic BP of the same person was 7.1 ± 7.6 and 7.5 ± 8.4 mm Hg, respectively (not

*Pearson's χ^2 test.

ANC, antenatal check-up; FWV, Family Welfare Visitor; SC, satellite clinics; UH&FWC, union health and family welfare centre.

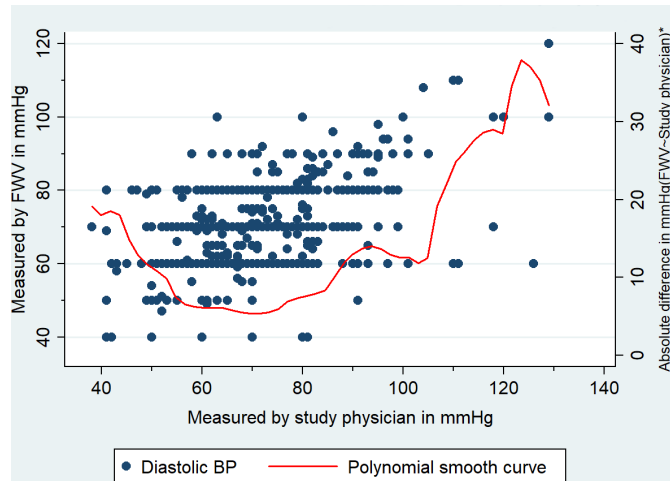

Figure 1 Diastolic BP: recorded by FWV versus study physician. BP, blood pressure; FWV, Family Welfare Visitor.

presented in the table). The polynomial smooth curve of the absolute differences between the study physician and FWV's measurement shows larger differences (>10 mm Hg) when the 'true' diastolic pressure was higher than 100 mm Hg or 'true' systolic pressure was higher than 160 mm Hg. The difference also widened when 'true' diastolic pressure was below 50 mm Hg or 'true' systolic pressure was below 100 mm Hg.

Urine assessment

Although there was high correct identification of 'no protein' in urine, only 27% of those who had 'some protein' were accurately diagnosed by FWVs (figure 3).

Status of hypertensive disorders of pregnancy

The 'true' prevalence for gestational hypertension, pre-eclampsia and severe pre-eclampsia diagnosed by the study physicians, was 2.1%, 1.9% and 1.0%, respectively (table 4). The numbers of cases identified by the FWVs were substantially lower than the 'true' prevalence for all three types of hypertensive disorders. No woman was

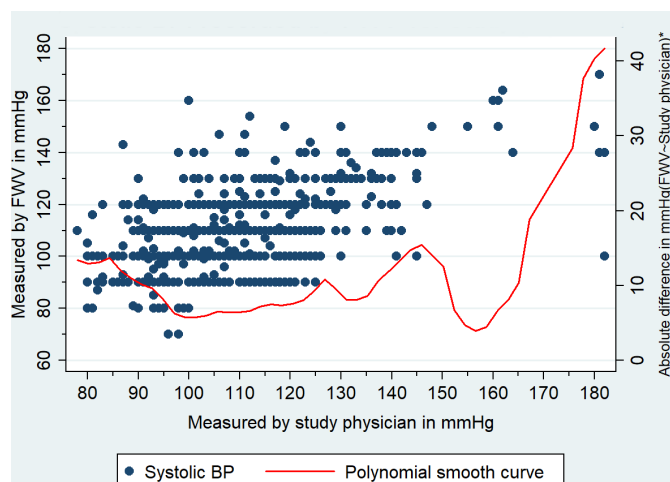

Figure 2 Systolic BP: recorded by FWV versus study physician. BP, blood pressure; FMV, Family Welfare Visitor.

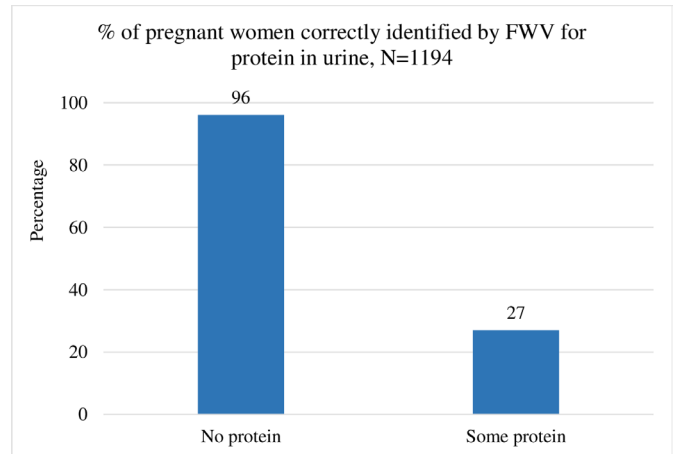

Figure 3 Protein in urine: accurately diagnosed by FWV. FMV, Family Welfare Visitor.

diagnosed with eclampsia by the study physician or FWV. Although the numbers are too small to compare, the FWVs could detect a higher proportion of cases of hypertensive disorders if they provided care in UH&FWCs than in satellite clinics.

Validity of the diagnosis of hypertensive disorders of pregnancy

FWV's diagnosis recorded in ANC register

Only in 3%, 7% and 25% of true cases of gestational hypertension, pre-eclampsia and severe pre-eclampsia, respectively, FWVs made a correct diagnosis during ANC (table 5). Per cent agreement for the diagnosed cases of hypertensive disorders of pregnancy is 9% and kappa statistics is 0.05 (p value 0.0125). For identification of any hypertensive disorders, sensitivity and PPV is only 14% and 50%, respectively. For identification of pre-eclampsia or severe pre-eclampsia or eclampsia, sensitivity and PPV are 18% and 80%, respectively. In both cases, specificity is high (>99%).

Post-hoc diagnosis based on FWV's assessment of BP and urine

When the diagnosis was made by applying the algorithm present in national protocol based on the two diagnostic criteria (elevated BP and protein in the urine) measured by FWVs and status of three danger signs assessed by study physicians the accuracy of diagnosis (ie, the percentage of 'true' cases accurately diagnosed), was markedly increased from that of the FWVs' original diagnosis of the conditions (table 5). For instance, at least 63% of 'true' cases of severe pre-eclampsia could be diagnosed if the protocol had been applied correctly by an FWV based on her assessment of BP and urine. The per cent agreement also improves from 9% to 29% and kappa statistics is 0.19 (p value <0.0001). Moreover, in this scenario, both sensitivity and PPV of diagnosing 'any hypertensive disorder' and 'pre-eclampsia and/or severe pre-eclampsia' are markedly increased.

Management provided by FWV

The women who were diagnosed to have any hypertensive disorders of pregnancy by FWVs were more likely to be counselled on at least one danger sign of pre-eclampsia (severe headache, blurring of vision and upper abdominal pain) than those without such diagnosis (41% vs 19%, *p* value 0.008). The FWVs provided antihypertensive drugs only for those with the diagnosis of gestational hypertension and pre-eclampsia (table 6). All four cases of severe pre-eclampsia were given a loading dose of intramuscular magnesium sulphate and three among them were referred to a higher facility.

DISCUSSION

Our study identified gaps in diagnosing hypertensive disorders of pregnancy during ANC in community-level satellite sessions and at primary healthcare centres in three districts of Bangladesh where USAID funded MaMoni HSS project intervened to improve maternal healthcare services. The undiagnosed or misdiagnosed cases could be linked with inadequate and inaccurate screening procedures performed by the health workers called FWVs. The study also observed inadequate history taking, inaccuracy in BP measurement and/or recording, and urine assessment for protein. A small proportion of the women who required antihypertensive drugs or counselling on disease management received such. All the detected cases of severe pre-eclampsia received the first dose of injectable magnesium sulphate as per the protocol.

The 'focused ANC package' by the WHO emphasised BP measurement and urine assessment during all ANC visit irrespective of gestational age to screen hypertensive disorders of pregnancy.^{19 30} In our study, nearly all women had their BP measured and about three-fourths had their urinary protein assessed. The MaMoni HSS project trained FWVs on diagnosis and management of pre-eclampsia and eclampsia before the study and the training could have influenced the high coverage of the screening procedures performed by the FWVs. Detection of hypertensive disorders of pregnancy, however, requires

screening for maternal comorbidities and proper history taking for danger signs of pre-eclampsia and convulsion during the current pregnancy, which was observed inadequate in our study. Nevertheless, the poor quality of ANC is consistent with that in other low/middle-income (LMIC) countries including Bangladesh.^{20 31} The practice was also significantly lower when the women received ANC in satellite or outreach sessions compared with in-facility antenatal services as found in another study conducted in rural Bangladesh.³² The satellite or outreach sessions are often hosted at the household of local rural elites on their acceptance and the health workers providing ANC in UH&FWCs need to carry all the necessary equipment and register books from the UH&FWC to the place of satellite sessions on the designated day of the week.¹⁴ Due to the makeshift nature of the satellite clinics, access to clean toilet facilities and provision of adequate privacy during physical examinations are often difficult to ensure at the service delivery points.³³ Despite having the required equipment for ANC, poorer readiness of satellite clinics might result in poorer performance of some critical components of ANC such as assessments of danger signs, BP measurement and urine assessment at those clinics than in the health facility.^{20 33}

Initiatives to improve quality of care often focus on bridging the coverage gap of specific activities by the health workers rather than focusing on the validity of the performed activities or developing reliable screening tools.^{31 34} For instance, BP measurement and urine assessment are two key diagnostic criteria for hypertensive disorders of pregnancy, yet their accurate ascertainment receives low priority in the training schemes for health workers in LMICs.³⁵ Our study found inconsistency in measured BP between the health workers' assessment and the 'true' value especially when the BP was beyond the normal range. This might allude to the tendency of the FWVs to record BP within the normal range without accurately measuring the BP of the ANC client. The study also detected terminal digit bias for both systolic and diastolic BP recordings, that is, the tendency to report the values ending in zero. One study suggests that the occurrence of recordings ending in zero

in more than 30% cases, in general, indicates imprecise and inaccurate recording.³⁶ Periodic checking of the ANC registers for terminal digit bias by the supervisors could minimise such practice.

Despite the overall low sensitivity and PPVs for detecting hypertensive disorders of pregnancy by the FWVs, our study found an increase in these parameters when the algorithm present in the pre-eclampsia protocol was applied to diagnose the disease condition using the recordings of the screening tests performed by FWVs. This indicates either poor adherence to the evidence-based guideline or improper interpretation of the national protocol by the FWVs while reaching a diagnosis. Unavailability of the ANC protocol in 16 out of the 26 assessed health facilities could further worsen the knowledge gap of the health workers regarding the disease diagnostic criteria. A landscape-analysis on pre-eclampsia and eclampsia conducted in Bangladesh concluded that pre-eclampsia/eclampsia guideline was not available in any of the assessed community-level primary healthcare centres, that is, UH&FWCs and only 8% of health workers working there knew that a national guideline on diagnosis and management of pre-eclampsia/eclampsia existed.¹⁵ Although we have not assessed the reasons for the unavailability of the ANC protocol, lack of regular monitoring of the presence and use of guidelines in community level health facilities and lack of knowledge of the health workers about the content of the guidelines are some critical barriers to maintaining and keeping the guidelines in the facility.^{18 35 37} In addition to putting effort from the central level to make the guidelines available in health facilities, the ANC providers should be made aware of the diagnostic criteria of hypertensive disorders of pregnancy and trained to accurately assess danger signs, measure BP and urinary protein. A review paper on improving the quality of care in LMICs suggested that capacity development training should also maintain strong supportive supervision, along with the provision of on-site feedback based on health workers' performances, and audit of ANC registers and case reports to improve health workers' adherence to the evidence-based guidelines.³⁸

In our study, a subtotal of 16 'true' cases of severe pre-eclampsia was identified by the study physicians and these cases required the first dose of magnesium sulphate injection before their referral to a higher-level facility. Since only four of them were correctly identified by the FWVs, the rest received no magnesium sulphate injection due to the missed diagnosis of the cases. The study physicians, however, had sent these women back to the FWV for re-evaluation and guaranteed that they received appropriate care on ethical grounds. Counselling regarding the hypertensive diseases of pregnancy or the provision of antihypertensive drugs to detected cases was also inadequate. The failure in the timely management of hypertensive disorders of pregnancy, therefore, poses a serious challenge in preventing maternal morbidity and mortality in LMICs. Besides improving the knowledge and skill of the ANC providers, prediction of risk and detection of cases can be aided by initiating a computerised clinical decision support system (CDSS)

Table 6 Management of hypertensive disorders identified by FWV during antenatal check-up at union health and family welfare centre

which has been proven effective for improved provider-care seeker communication and clinical decision making.³⁹ Unlike in developed countries, where CDSS was effective in improving health workers' performances,⁴⁰ implementation of such technology in LMICs could be challenging in the context of poor availability of health information, inadequate infrastructure and limitation of skilled human resources.⁴¹ Since the adoption of the national eHealth policy in 2011,⁴² Bangladesh is progressing with establishing electronic management information system (e-MIS) in the health facilities and has started to provide community health workers with computer tablets or smartphones to deliver essential health services on the pilot basis.⁴³ The integration of CDSS into the e-MIS initiative could contribute to the sustainability of improving the quality of care during ANC, and thus the screening of hypertensive disorders. Further research is needed to identify and address potential constraints for smooth implementation of the decision support technology to ensure proper detection and management of gestational hypertensive disorders in Bangladesh and other LMICs.

CONCLUSION

Consistent application of the national protocol supports clinical-decision making by health workers during the provision of ANC. Efforts should be directed at accurate application and interpretation of the national protocols or guidelines by health workers as a prerequisite for task shifting for the detection and management of hypertensive disorders of pregnancy at primary level health facilities and outreach centres. The training of ANC health workers should emphasise the risk assessment of pregnant women with a practical demonstration on assessing the diagnostic criteria and management of eclampsia and pre-eclampsia. Strengthening the monitoring and supervision can further improve the screening of pre-eclampsia and severe pre-eclampsia and timely management of such cases to prevent eclampsia.

Patient consent for publication Not required.

Ethics approval The study protocol was reviewed and approved by the Ethical Review Committee (ERC) of the International Center for Diarrhoeal Disease Research, Bangladesh (icddr,b) (protocol number PR-17084). Permission was taken from the Ministry of Health and Family Welfare and health managers of the selected health facilities were informed about the study. Written informed consent was obtained from the FWVs and verbal consent was sought from ANC service recipients during clinical observations. The respondents participated in the study voluntarily and had the right to withdraw themselves from the study at any time even after giving the consent. Privacy, anonymity and confidentiality of the data were strictly practised and restrictions on access to data were enforced.

Provenance and peer review Not commissioned; externally peer reviewed.
