**ABSTRACT:** Multiple system atrophy (MSA) is a rare and fatal neurodegenerative disease with limited symptomatic treatment options. Aggregation of  $\alpha$ -synuclein in oligodendrocytes is believed to be a central mechanism of the neurodegenerative process. PD01A and PD03A are 2 novel therapeutic vaccine candidates containing short peptides as antigenic moieties that are designed to induce a sustained antibody response, specifically targeting pathogenic assemblies of  $\alpha$ -synuclein. The objectives of the current study were to evaluate primarily the safety and tolerability of PD01A and PD03A in patients with early MSA. Thirty patients (11 women) were

randomized to receive 5 subcutaneous injections of either PD01A (n = 12), PD03A (n = 12), or placebo (n = 6) in this patient- and examiner-blinded, placebo-controlled, 52-week phase 1 clinical trial (ClinicalTrials.gov identifier: NCT02270489). Immunogenicity and clinical scores were assessed as secondary objectives. Twenty-nine patients reported a total of 595 treatment-emergent adverse events (mild or moderate, n = 555; severe, n = 40). Treatment-related adverse events included 190 injection-site reactions typically observed in vaccination trials with similar per-subject incidence in the treatment groups over time.

Sustained IgG titers were observed in the PD01A-treated group, and 89% of treated patients developed a PD01-specific antibody response after receiving all injections. Induced antibodies displayed clear reactivity to the  $\alpha$ -synuclein target epitope. Titers and antibody responder rate (58%) were lower in the PD03A-treated group. In conclusion, both PD01A and PD03A were safe and well tolerated. PD01A triggered a rapid

and long-lasting antibody response that specifically targeted the  $\alpha$ -synuclein epitope. © 2020 The Authors. *Movement Disorders* published by Wiley Periodicals LLC on behalf of International Parkinson and Movement Disorder Society.

**Key Words:** MSA;  $\alpha$ -synuclein; active immunization; treatment

Multiple system atrophy (MSA) is a debilitating and fatal neurodegenerative disease characterized by a variable combination of autonomic failure, parkinsonism, and cerebellar and pyramidal features. The estimated prevalence of this rare disease ranges between 1.9 and 4.9 per 100,000.<sup>1</sup> Clinically, 2 major subtypes are distinguished, one with predominant parkinsonism (MSA-P) and one with dominating cerebellar impairment (MSA-C). Both have poor prognosis. Current treatment options are limited and provide only some symptomatic relief. Therefore, disease-modifying therapies remain an urgent unmet need.<sup>2,3</sup>

The neuropathological hallmark is the accumulation of  $\alpha$ -synuclein in oligodendrocytes, forming glial cytoplasmic inclusions,<sup>4-6</sup> qualifying MSA as a synucleinopathy together with Parkinson's disease and Lewy body dementia. The origin of  $\alpha$ -synuclein in glial cytoplasmic inclusions remains under debate, and the exact mechanisms underlying the pathogenesis are only incompletely understood. Nevertheless, the accumulation of  $\alpha$ -synuclein aggregates and their cell-to-cell propagation are believed to play a central role at molecular and cellular levels in the neurodegenerative process in MSA.<sup>1,3,7-10</sup>

As a consequence,  $\alpha$ -synuclein-targeting therapies are currently considered a promising approach to prevent disease progression in MSA.<sup>3,11</sup> One suitable approach being investigated is specific active immunotherapy. This involves immunization with short peptides (AFFITOPEs) mimicking the amino acid sequence of a segment of the target protein.<sup>12</sup> The respective AFFITOPE is conjugated to the carrier protein keyhole limpet hemocyanin (KLH) and is absorbed to aluminum hydroxide. The carrier protein provides the required T-helper epitopes for the induction of a long-lasting and boostable antibody response, whereas the antigenic component (ie, the AFFITOPE) operates solely as a B-cell epitope and is responsible for the specificity of the humoral immune response. Specific active immunotherapy against  $\alpha$ -synuclein has been designed to induce a long-lasting antibody response specific for aggregated  $\alpha$ -synuclein species and has been shown to interfere with  $\alpha$ -synuclein pathogenic mechanisms.<sup>11-13</sup>

The specific active immunotherapy candidates PD01A and PD03A have proven to be highly immunogenic and to induce  $\alpha$ -synuclein aggregate-specific antibodies in mice.<sup>14,15</sup>

In a transgenic mouse model of MSA, active immunization with PD01A induced specific antibodies against  $\alpha$ -synuclein and mitigated the accumulation of  $\alpha$ -synuclein aggregates, which was associated with reduced neurodegeneration.<sup>14</sup>

Here, we assessed in a first-in-human trial, the safety, tolerability, and immunogenicity of the 2  $\alpha$ -synuclein targeting AFFITOPE vaccines PD01A and PD03A in patients with early MSA.

## Methods

### Study Design

This bicenter, randomized, patient- and examiner-blinded, placebo-controlled, parallel-group phase 1 clinical trial assessed safety, tolerability, and immunogenicity of repeated subcutaneous injections of either PD01A, PD03A or placebo in weeks 0, 4, 8, 12, and 36 in patients with early MSA. Patients were enrolled between December 2014 and March 2016 at the 2 sites of the French Reference Center for MSA at the University Hospitals in Bordeaux and Toulouse. This study received ethical approval (CPP Sud-Ouest et Outre-Mer III, 2014/65) and was conducted according to the Declaration of Helsinki (EudraCT: 2014-000567-40, ClinicalTrials.gov identifier: NCT02270489).

Patients between 30 and 75 years with early MSA (defined as  $\leq 4$  years from symptom onset) fulfilling current consensus criteria for a diagnosis of possible or probable MSA<sup>16</sup> were randomized to receive treatment with either PD01A (n = 12), PD03A (n = 12), or placebo (n = 6); see Figure 1. Participants had no major cognitive impairment (Montreal Cognitive Assessment score at screening  $\geq 21$ ) and were on stable medications for at least 30 days at the screening visit. Treatments for concomitant illnesses had to remain stable during the entire study period. In addition, efforts were made to keep treatments for MSA symptoms (eg, dopamine replacement therapy, midodrine, fludrocortisone, laxatives, antidepressants) as stable as possible during the entire study period. Patients were randomized according to the permuted blocks method with fixed block size. The randomization sequence was computer-generated by the trial sponsor's statistician. Patients were randomized accordingly by a responsible unblind person

FIG. 1. Study design and patient enrollment. [Color figure can be viewed at [wileyonlinelibrary.com](http://wileyonlinelibrary.com)]

(designated staff member at each study site without any involvement in the study assessments).

According to the request of the French regulatory authorities (Agence Nationale de Sécurité du Médicament), enrollment was stopped after the 6th and 16th patient had completed the 3 primary immunizations for interim safety assessments. If a suspected unexpected serious adverse reaction was reported, the Data Safety Monitoring Board was to be consulted to evaluate the event and to provide recommendations concerning continuation of the trial.

### Study Treatments

PD01A, PD03A, and placebo were administered 5 times via subcutaneous injection in weeks 0, 4, 8, 12, and 36. Injections of PD01A and PD03A contained the AFFITOPE peptide (either PD01 or PD03)-KLH conjugates adjuvanted with aluminum hydroxide (Alhydrogel) in phosphate-buffered saline (PBS), whereas placebo injections consisted of aluminum hydroxide in PBS only. The administered dose of 75 µg corresponds to the amount of immunizing peptide in the conjugate. The investigational medicinal product (IMP) was prepared on site by the responsible unblind staff member (see above).

### Study End Points

The primary end point was safety and tolerability as determined by withdrawal criteria, adverse events (AEs), serious adverse events (SAEs), physical and neurological examination results, vital signs, body mass, safety reads of brain magnetic resonance imaging (MRI), and laboratory assessments. Secondary end points included immunogenicity (ie, the change from baseline of antibody titers specific for the immunizing peptides PD01A and PD03A and the targeted  $\alpha$ -synuclein epitope) and clinical rating scales (ie, the change from baseline in Unified MSA Rating Scale [UMSARS] I–IV, Geriatric Depression Scale [GDS], and Composite Autonomic Symptom Score 31 [COMPASS 31] scores).

Safety monitoring performed at every study visit included assessments of local site reactions, vital signs, physical and neurological examinations, and blood laboratory testing. Adverse events were coded using MedDRA dictionary version 18.1. Grading of injection-site reactions was performed according to the US Food and Drug Administration Guidance for Industry: “Toxicity Scale for Healthy Adult and Adolescents Patients Enrolled in Preventive Vaccine Clinical Trials” from 2007. Investigator-blinded brain MRI (high-field 3.0 T

with fast 3-plane localizer, T1-3-D-weighted, T2-3-D-weighted, and FLAIR-3D sequences) and clinical assessments (UMSARS I-IV, GDS, and COMPASS 31) were performed at baseline, week 26, and the end of study. Lumbar puncture was performed at baseline and week 40. The total study duration was 52 weeks.

**Specific Active Immunotherapy IgG Response**

For immunogenicity testing, serum samples were serially diluted (1:3 dilution steps) and evaluated by an external provider (eBioscience, Vienna) using an ELISA validated to specifically detect IgG antibodies. Titers were determined for reactivity with either PD01 or PD03, with the native epitope on the target  $\alpha$ -synuclein protein, an irrelevant control peptide, and the carrier protein KLH (to confirm patients' immune competence). A serial dilution of a human IgG pool coated to the ELISA plate was used as a calibration curve, and results are presented as geometric mean end-titers. End-titers were defined as last serum dilution that gave a signal that was higher than the signal of the calibration curve at penultimate dilution. Immune responders (seroconversion) were defined as patients with a PD01 or PD03 peptide titer ratio  $\geq$  4-fold relative to baseline.<sup>17</sup>

**Statistical Analysis**

The safety population was defined as patients enrolled into the study and receiving at least 1 immunization (identical to the intention-to-treat population [ITT]).

Statistical analyses were performed based on the 3 treatment groups (frequency table for categorical data and descriptive statistics for continuous data). All statistical tests in this study were regarded as hypothesis-generating and *P* values as descriptive. The sample size of this exploratory study was based on a clinical rationale; no formal sample size calculation was performed.

Immune parameters were statistically compared between treatment groups at the different visits using analysis of covariance with baseline as covariate based on log-transformed data (geometric mean and 95% CI). For the comparison of baseline UMSARS II (motor examination) scores and their change over time, a mixed model for repeated measurements was used to obtain the average treatment effect over the whole study period with the fixed-effects parameter baseline, treatment, and time as well as treatment-by-time interaction. Depending on normality of data, a paired *t* test or a Wilcoxon signed-rank test was performed to compare the changes of UMSARS I/IV, GDS, and COMPASS 31 scores from baseline to study end for each treatment group.

## Results

### Demographics

Thirty patients were enrolled (11 women) with a median age of 61 years and a mean interval of 2.75 years since symptom onset (0.75 years since MSA diagnosis). Baseline characteristics with corresponding clinical scores are presented in Table 1. Twenty-five patients received at least 1 concomitant symptomatic medication, mostly dopamine replacement therapy with 5 subjects receiving a combination of several drugs.

### Safety

The safety population included all 30 enrolled subjects. A total of 595 treatment-emergent adverse events (TEAEs) were reported by 29 patients (Table 2). Fifteen serious adverse events (SAE) were reported in this study in eleven patients (10 SAEs in 7 PD01A patients, 2 SAEs in 2 PD03A patients, and 3 SAEs in 2 placebo-treated patients; Table S1).

Twenty-four patients completed the trial, and 6 discontinued the study treatment. Reasons for study discontinuation were death (2 patients), withdrawal shortly followed by death (1 patient), fatigue (2 patients), and concomitant disease (1 patient). The reported cause of death was worsening of MSA-related conditions for 2 patients and pulmonary embolism for 1 (pulmonary embolism and MSA diagnosis were confirmed in this patient by autopsy). All 3 deaths were considered unrelated to the active treatments after a detailed investigation involving the French Competent Authority (Agence Nationale de Sécurité du Médicament) and the Data Safety Monitoring Board.

The vast majority of reported TEAE were of mild or moderate intensity, leaving 40 adverse events classified as severe (Table 2). The number of TEAEs and treatment-related AEs per subject was very similar in all treatment groups. Overall, there were 190 local reactions and 200 systemic reactions when including only events with an incidence >10% of subjects (Table S2). There were 17 injection-site reactions after the first

immunization and 52 after the second immunization, followed by a plateau in both absolute number and affected subjects. Severe local reactions were sporadically observed.

There were 277 adverse events classified as related to study medication (possibly, probably, or certainly related), of which 190 were injection-site reactions, typically observed in vaccination trials, and systemic events such as fatigue, headache, and nausea. The number of injection-site reactions per sex was similar for PD01A, but higher for women in the PD03A and placebo treatment groups (PD01A, 8.6 ISR/woman vs 8.8 ISR/man; PD03A, 9.3 ISR/woman vs 5.4 ISR/man; placebo, 11.0 ISR/woman vs 6.8 ISR/man); see Table S3.

Compatible with the underlying disease, vital signs, physical and neurological examinations, and some hematology and clinical chemistry laboratory results were abnormal and considered clinically significant at baseline and during the study. Brain MRI and cerebrospinal fluid (CSF) assessments did not reveal any sign of an adverse neuroinflammatory response induced by the IMP.

### Antibody Titers

Both active treatments, PD01A and PD03A, induced a sustained IgG antibody response against the immunizing peptides PD01 and PD03, respectively (Fig. 2A,B). Titers peaked in week 12 (4 weeks after the third immunization) and subsequently declined, with a half-life of approximately 12 weeks. The geometric group mean titer against the immunizing peptide increased significantly in the PD01A-treated group compared with placebo by a factor of 114, from 1:41 at baseline to 1:4673 in week 12 ( $P = 0.0078$  change from baseline; Fig. 2A) and in the PD03A-treated group compared with placebo by a factor of 14.6, from 1:94 to 1:1379 ( $P = 0.0179$  change from baseline; Fig. 2B). After 3 priming injections, 9 of 11 patients in the PD01A group (82%) and 7 of 12 patients in the PD03A group (58%) met the predefined cutoff for seroconversion. The boost immunization in week 36 reactivated the

**TABLE 2.** Overview of TEAE by severity and relation to study medication

Parameter		PD01A (n = 12)	PD03A (n = 12)	Placebo (n = 6)	Total (n = 30)
All TEAE	Subjects (events)	11 (231)	12 (217)	6 (147)	29 (595)
Mild TEAE		11 (116)	12 (108)	6 (101)	29 (325)
Moderate TEAE		11 (94)	11 (92)	6 (41)	28 (227)
Severe TEAE		8 (19)	7 (16)	2 (5)	17 (40)

AE, adverse event; treatment-related AE, AE classified as possibly, probably, or certainly related to the IMP; SAE, serious adverse event; TEAE, treatment-emergent AE; data from ITT population.

**FIG. 2.** PD01, PD03, and  $\alpha$ -synuclein target epitope-specific titers over time. Primary immune response to the immunizing peptides PD01 (A), PD03 (B), and the  $\alpha$ -synuclein target epitope (C). Bars represent the 95% confidence intervals. Arrows indicate times of injection. \* $P < 0.05$  compared with placebo (change from baseline); \*\* $P < 0.01$  compared with placebo (change from baseline). [Color figure can be viewed at [wileyonlinelibrary.com](http://wileyonlinelibrary.com)]

antibody response, with peak titers achieved 4 weeks after the administration, resulting in geometric group mean titers of 1:6740 in the PD01A group ( $P = 0.0066$  compared with placebo, with 8 of 9 patients showing seroconversion — 89%) and 1:1080 in the PD03A

group ( $P = 0.0437$  compared with placebo, with 7 of 12 patients classified as serological responders — 58%). In both groups, the booster immunization triggered a long-lasting antibody response, which could be observed until the end of the study.

**TABLE 3.** Clinical scores over time by treatment group

<sup>a</sup>Number of evaluated subjects at baseline/V5/V8; data from ITT population.

Antibody titers against the  $\alpha$ -synuclein target epitope were lower than those measured against both immunizing peptides, but the time profile of antibody development was very similar for all. Following immunization with PD01A peptide, antibody titers against the  $\alpha$ -synuclein target epitope increased from 1:30 at baseline to 1:324 in week 12 ( $P = 0.0097$  compared with placebo; Fig. 2C) and 1:562 in week 40 ( $P = 0.0273$  compared with placebo; Fig. 2C). Antibody levels against the  $\alpha$ -synuclein target epitope did not increase significantly in the PD03A group, reaching geometric group mean titers of 1:62 and 1:90 in weeks 12 and 40, respectively (Fig. 2C). As expected, antibody reactivity to the immunizing PD01A and PD03A peptides and to the  $\alpha$ -synuclein target epitope did not change over time in the placebo group (Fig. 2A–C).

### Clinical Rating Scores

Results for UMSARS I–IV, GDS, and COMPASS 31 over time are summarized in Table 3. UMSARS I and II scores increased significantly during the trial period in all 3 treatment groups (PD01A: change UMSARS I [V0–V8],  $P = 0.0261$ ; change UMSARS II [V0–V8],  $P = 0.0322$ ; PD03A: change UMSARS I [V0–V8],  $P = 0.0031$ ; change UMSARS II [V0–V8],  $P = 0.0043$ ; placebo: change UMSARS I [V0–V8],  $P = 0.0028$ , change UMSARS II [V0–V8],  $P = 0.0033$ ). Differences between groups were not significant, and observed changes in activities of daily living and motor symptoms were within the expected ranges because of disease progression in all groups.

UMSARS IV scores increased within the PD03A treatment group (change V0–V8,  $P = 0.0261$ ), whereas no significant changes were observed for GDS and COMPASS 31 for all treatment groups.

### Discussion

The primary objective of this first-in-human randomized phase 1 trial was to evaluate the safety and tolerability of repeated administrations of 2 specific active immunotherapies, PD01A and PD03A, in patients diagnosed with early MSA compared with placebo. The immunization schedule had been designed to both evaluate the primary antibody response after the first immunizations administered within 12 weeks and the long-lasting antibody response after the boost immunization in week 36.

The overall safety profile showed no substantial difference between the 3 treatment groups. The 3 deaths reported in this study were all classified as unrelated to the IMP after external review, similar to all SAEs, although the total number of SAEs was higher in the PD01A group. There was a higher number of injection-site reactions and a lower number of systemic adverse events in the active treatment groups compared with placebo. The high number of reported adverse events was expected because of the severity of the underlying disease itself, possible adverse events of the concomitant symptomatic medications, and the TEAEs caused by the active immunizations. The TEAEs classified as related to PD01A and PD03A were expected and generally well tolerated including fatigue, headache, nausea, and injection-site reactions. The incidence of local reactions increased after the first immunization, but remained relatively constant after the second immunization with no evidence for cumulative severity.

The detected antibody response triggered by PD01A was higher than that of PD03A. Immunization with

PD01A resulted in a significant increase in titers against the immunizing AFFITOPE PD01 peptide in week 12 (4 weeks after the third immunization), which translated to a humoral immune response against the  $\alpha$ -synuclein target epitope of approximately 1 order of magnitude lower. The antibody response increased rapidly following a booster injection in week 40 (4 weeks after the booster application), suggesting that the priming immunizations produced a significant memory effect, and antibody levels persisted until the end of the study. The observation of lower titers for the  $\alpha$ -synuclein target epitope compared with the immunizing AFFITOPE peptide may at least partially be explained by the binding of vaccine-induced antibodies to the target structure (ie, masking the number of detected antibodies). IgG titers monitored after PD03A application were lower than those observed for PD01A. The reasons for this observation are currently unclear, although impaired capacity of the immune system in the PD03A treatment group could be ruled out, as the immune response against the carrier protein KLH was almost identical in both active treatment groups.

No data are yet available about the level of  $\alpha$ -synuclein-specific antibodies in the brain required to achieve a therapeutic clinical effect. However, antibody levels in CSF and presumably also in the brain seem to be dependent on the antibody concentration in the circulation.<sup>18,19</sup> Furthermore, different antibody concentration dynamics induced either by active or passive immunotherapy might further influence the concentration of  $\alpha$ -synuclein-specific antibodies in the brain.

Our study has limitations. First, the small sample size allowed us to obtain first insights into the safety profile of PD01A/PD03A and potential efficacy measures in MSA patients, which will help design future clinical studies. However, the sample size was not sufficient to detect statistically significant differences, and the study was not designed to perform such tests. Second, blinding was limited to patients and examiners. However, the involvement of an unblind person for randomization and IMP preparation without any involvement in the study assessments, a similar number of TEAEs in all 3 treatment groups and the assessment of antibody titers after completion of the last study follow-up visit ensured successful blinding of patients and examiners throughout the trial.

In conclusion, disease-modifying or neuroprotective treatments remain an urgent unmet treatment need for MSA, and targeting  $\alpha$ -synuclein with specific active immunotherapy seems a promising strategy in this regard. The results of this trial in terms of safety, tolerability, and immune reaction of repeated administrations of 2 active immunotherapies, PD01A and PD03A, warrant further investigation of specific active immunotherapy in MSA patients. ■
