

Since January 2020 Elsevier has created a COVID-19 resource centre with free information in English and Mandarin on the novel coronavirus COVID-19. The COVID-19 resource centre is hosted on Elsevier Connect, the company's public news and information website.

Elsevier hereby grants permission to make all its COVID-19-related research that is available on the COVID-19 resource centre - including this research content - immediately available in PubMed Central and other publicly funded repositories, such as the WHO COVID database with rights for unrestricted research re-use and analyses in any form or by any means with acknowledgement of the original source. These permissions are granted for free by Elsevier for as long as the COVID-19 resource centre remains active.

Quality of life

## ABSTRACT

**Objective:** Several long-lasting health complications have been reported in previous coronavirus infections. Therefore, the aim of this study was to review studies that evaluated physical and mental health problems post-COVID-19.

**Methods:** Articles for inclusion in this scoping review were identified by searching the PubMed, Scopus, Web of Science and Google Scholar databases for items dated from 1 January to 7 November 2020. Observational studies evaluating physical health (musculoskeletal symptoms, functional status) or mental health status with a follow-up period longer than 1 month after discharge or after the onset of symptoms were included.

**Results:** This scoping review included 34 studies with follow-up periods of up to 3 months post-COVID-19. The most commonly reported physical health problems were fatigue (range 28% to 87%), pain (myalgia 4.5% to 36%), arthralgia (6.0% to 27%), reduced physical capacity (six-minute walking test range 180 to 561 m), and declines in physical role functioning, usual care and daily activities (reduced in 15% to 54% of patients). Common mental health problems were anxiety (range 6.5% to 63%), depression (4% to 31%) and post-traumatic stress disorder (12.1% to 46.9%). Greater fatigue, pain, anxiety and depression were reported in female patients and individuals admitted to intensive care. An overall lower quality of life was seen up to 3 months post-COVID-19.

**Conclusions:** This review highlights the presence of several physical and mental health problems up to 3 months post-COVID-19. The findings point to the need for comprehensive evaluation and rehabilitation post-COVID-19 to promote quality of life.

## 1. Background

Coronavirus disease 2019 (COVID-19) has spread throughout the world, leading to a global pandemic [1]. The World Health Organization (WHO) consequently declared COVID-19 to be a public health emergency of international concern [2]. A rapidly growing body of literature is available on the clinical presentations and treatments of the acute

phase of COVID-19. Common characteristics of the acute stage of the disease are fever, musculoskeletal symptoms (fatigue, myalgia, and joint pain), dry cough, dyspnea, gastrointestinal symptoms, and anosmia with or without ageusia [3].

Importantly, after viral infection different types of damage occur in multiple body organs, especially the brain [4]. In addition, peripheral and central inflammatory responses (neuroinflammation) may be

triggered by the infection, and can lead to long-lasting musculoskeletal problems, cognitive impairment, and psychological distress [5–8]. A review of severe acute respiratory syndrome (SARS) and Middle East respiratory syndrome (MERS) reported several long-lasting clinical complications that affect different aspects of health, including chronic fatigue, reduced physical capacity, muscles weakness, increased depression, anxiety, post-traumatic stress disorder (PTSD), and sleep problems [9]. An overall decline in quality of life has been observed as long as 1 year after major coronavirus outbreaks [9]. According to the WHO International Classification of Functioning, Disability and Health (ICF) framework, rehabilitation programs should be planned in order to improve individual functioning at three levels: (1) body function and structure, (2) activity and participation, and (3) environmental factors and personal factors to improve quality of life [10]. Current recommendations advise implementation of the ICF model in the fields of evaluation, diagnosis, and interventions. This makes it important to document post-COVID-19 physical and mental health consequences that affect quality of life, as a way to improve rehabilitation services and help healthcare organizations to plan efficient rehabilitation programs. Therefore, the aim of this study was to review studies on post-COVID-19 physical and mental health complications.

## 2. Methods

### 2.1. Study design

The methodological framework proposed by Arksey and O'Malley was used to conduct this scoping review [11]. The following five steps were used: a) identifying a clear research objective and search strategies, b) identifying relevant research articles, c) selecting research articles, d) extracting and charting data, and e) summarizing, analyzing, discussing, and reporting the results.

### 2.2. Identifying the review questions

The main review question was as follows: "What are the physical and mental health complications in adult patients post-COVID-19 infection?"

### 2.3. Literature search strategies

Studies for this scoping review were identified by searching the PubMed, Scopus, Web of Science and Google Scholar databases for items dated from 1 January 2020 to 7 November 2020. The search terms were ("COVID-19" OR "2019 novel coronavirus" OR "SARS-CoV-2" OR "2019-nCoV" OR "Coronavirus 2019") AND ("Follow up" OR "Discharge" OR "Post discharge" OR "Long-term effect" OR "Post-covid"). The PubMed syntax is shown in Appendix A.

### 2.4. Eligibility criteria

The following inclusion criteria were used: Original articles (observational studies such as cohort, cross-sectional and case series) that were peer reviewed or preprinted, that assessed physical health status (musculoskeletal symptoms, physical and/or functional performance) with functional tests or by questionnaire, that assessed mental health status, that evaluated patients after a follow-up period of at least 1 month after the onset of COVID-19 or after hospital discharge, and that were published in English. Studies were excluded if they were randomized clinical trials, review articles, guidelines and recommendations, protocol studies, or case reports; if they examined only clinical factors such as laboratory tests, cardiovascular, pulmonary, endocrine, renal, neurological disorders, or specific disease groups with coronavirus infection; if they included non-adult patients; and if they were published in a language other than English.

### 2.5. Identification and selection of studies

All studies involving adults with a confirmed diagnosis of COVID-19 were included in this review. After searching the databases, a total of 7398 articles were found. After 3802 duplicate articles were removed, the titles and abstracts of all remaining articles were screened by two independent reviewers (M.T., S.A.A.) in two steps. Subsequently, the same two reviewers independently screened the full texts of studies to verify that they met the eligibility criteria. In cases of disagreement, a third researcher was consulted (S.S.) to reach a final decision.

### 2.6. Data extraction from included studies

The data from all included studies were extracted by two independent reviewers (M.T., S.A.A.), and are presented in Tables 1 to 3. The data extracted for each article were author, study design, country, sample size, age, follow-up period, hospitalization period, outcomes and their measurements tools, prevalence of outcomes and mean (standard deviation [SD]) or median (interquartile range [IQR]) score of each outcome.

## 3. Results

### 3.1. Search results

Fig. 1 illustrates a Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) flow diagram for the process of searching and selecting eligible studies. We found 7398 studies by searching with syntaxes adapted to each database, and removed 3802 as duplicates. Titles and abstracts were screened for residual studies ( $n = 3596$ ), and 3503 of these were excluded based on irrelevant titles and/or abstracts, which left 93 studies. Full text screening showed that 59 studies did not meet the eligibility criteria, and so were excluded. Finally, 34 studies met our inclusion criteria and were included in this review: 29 studies were peer reviewed and five studies were preprints.

### 3.2. Characteristics of included studies

The characteristics of all 34 included studies are presented in Tables 1 to 3. The total number of participants in all 34 studies was 8932, with sample sizes ranging from a case series of 14 patients to a retrospective cohort study of 2113 patients. Among all patients included, 56.3% were women and 43.7% were men. The majority of studies were from China ( $n = 10$ , 29.5%) and Italy ( $n = 7$ , 20.6%). The designs of these studies were 20 cohort, 10 cross-sectional, and four case series. Post-infection follow-up times differed among studies, ranging from 1 to 3 months after symptom onset or hospital discharge, and the mean duration of hospitalization was 15.86 days. The overall Health related Quality of Life (HRQOL) score (Table 1) was reported in 13 studies, with six studies using the European Quality of Life 5-Dimensions instrument (EQ-5D) or European Quality of Life 5-Dimensions instrument, 5-levels (EQ-5D-5L), three studies using the Short Form Health Survey (SF-36), and three studies using St. George's Respiratory Questionnaire (SGRQ). Physical health status was evaluated in 23 studies, and was commonly assessed as fatigue/asthenia/tiredness (16 studies), pain including joint pain/arthritis and myalgia (14 studies), or functional status based on valid questionnaires (6 studies) or exercise capacity tests such as the six-minute walk test (6MWT) or one-minute sit to stand test (STS) [12–15] (Table 2). Mental health status was assessed in 18 studies, in which the mental health symptoms evaluated most frequently were anxiety (11 studies), depression (10 studies), PTSD (7 studies), sleep problems (8 studies), and cognition problems (8 studies) (Table 3). Psychological symptoms were evaluated with single-item questions or valid instruments (Tables 1 and 3).

### 3.3. Health status

Overall health status that was evaluated with the HRQOL questionnaire, and was found to be lower post-COVID-19 compared to the normal population [12,16]. Post-COVID-19 patients had slight to moderate declines in HRQOL [15–20]. Intensive care unit (ICU) admission had a significant negative effect on HRQOL scores [15–17,21]. One study reported that early physical and pulmonary rehabilitation within 72 h of ICU admission could be effective in improving HRQOL at 1 month and 3 months after hospital discharge [12]. Specific categories of physical and mental health status according to the HRQOL questionnaire are covered in the next two sections, along with the results of other measurements related to physical and mental health.

### 3.4. Physical health status

#### 3.4.1. Musculoskeletal symptoms

Fatigue was reported in 28% to 87% of individuals after coronavirus infection. This complication was observed in both hospitalized and nonhospitalized patients, and in those admitted to in-patient wards and the ICU [16,19,22,23]. Seven studies assessed the association between fatigue and COVID-19 severity [16,21,24–26]; four found greater fatigue in severely ill individuals [16,21,26], and one study reported greater fatigue or physical decline with longer durations of hospital stay [27]. Five studies found normal laboratory tests at follow-up, and suggested there was no association between fatigue and laboratory parameters such as inflammatory markers, cell turnover (leukocyte, neutrophil or lymphocyte counts, neutrophil-to-lymphocyte ratio, lactate dehydrogenase, C-reactive protein) or pro-inflammatory molecules (IL-6 or soluble CD25), ferritin or D-dimer [15,16,23,24]. Fatigue was reported in a greater proportion of women [21,24,27] and individuals with psychological problems [21,24].

Across all studies, the prevalence of post-COVID-19 myalgia was 4.5–36%, and the prevalence of post-COVID-19 arthralgia was 6.0–27%. Only one study from China reported no pain at follow-up [25]. Pain was evaluated with health-related questionnaires (EQ-5D, EQ-5D-5L and SF-36), and patients reported slight to moderate pain, except in one study that reported moderate to severe pain in 51.6% of individuals admitted to the ICU [28]. Overall, pain was reported by a greater percentage of recovering individuals post-COVID-19 who experienced severe illness in the acute stage and required hospitalization [16,19,26,29,30]. A larger proportion of individuals with anxiety and depression reported musculoskeletal symptoms compared to their counterparts without these diagnoses [15,21,31]. The studies included in this review reported conflicting results regarding the association between comorbidities and the presence of musculoskeletal symptoms post-COVID-19 [22–24,26,30], although most reported no association [22,24,30]. Muscle weakness was evaluated in one study that reported ICU-acquired weakness in 18.42% of individuals post-COVID-19 at 3 months' follow-up [12]. Another study found that respiratory muscle strength in post-COVID-19 patients was lower at inspiration (49.1%) and expiration (22.8%) 1 month after hospital discharge [14].

### 3.5. Physical and functional health status

Four studies evaluated functional capacity with the 6MWT, with results ranging between 180 to 561 m from 1 to 3 months post-COVID-19 [12–15]. Two studies reported no decrease in oxygen saturation during functional capacity tests (6MWT and STS); however, excessive fatigue was found in some individuals [15,16]. One study found very low 6MWT results in individuals with persisting hyperferritinemia [13].

Physical health status was most often evaluated with quality of life questionnaires (EQ-5D, EQ-5D-5L, SF-36 and SGRQ). Only two studies evaluated functional status and level of physical activity with other instruments such as the Barthel index [12], functional independence measure (FIM), or post-COVID-19 functional status scale (PCFS) [32].

**Table 2**

Physical health outcomes in COVID-19 survivors.

Author	Study design	Country	Sample size (N) Male/Female	Age (years) Mean (SD)	Follow-up period month/or days Mean (SD)	Hospitalization period (days) Mean (SD)	Outcomes (Measurement tools)	Results (Mean, SD), Prevalence of outcomes n/N (%)

usual activities were reported to be reduced in 15% to 54% of individuals after their coronavirus infection [12,15,17–19,21,28,29,33]. Five studies reported a decline in physical activity especially for usual care and daily activities in individuals admitted to the ICU [12,15,16,21,28]. Three studies reported greater declines in physical role functioning (participation in life despite physical limitations) compared to other components of physical health status [16,29,34].

### 3.6. Mental health status

The most frequent mental health symptom reported in the studies included in this review was anxiety, with post-COVID-19 prevalences ranging from 6.5% to 63%. The second most frequent psychological symptom was depression, with prevalences ranging between 4% and 31% at follow-up times longer than 1 month post-COVID-19. One third of the patients in Italy and 41.3% of those in Iran had both depression and anxiety after hospital discharge [17,31]. Another common post-COVID-19 mental health problem was PTSD, with prevalences ranging from 12.1% to 46.9%. The severity of COVID-19 was related to the severity and prevalence of mental health symptoms [16], with anxiety and PTSD being significantly more frequent in patients admitted to the ICU compared to wards [19,21,31,36]. Additional mental health symptoms were sleep problems, with prevalences ranging between 17.7% to 30.8% [16,19,27], and cognitive-functional problems, reported in 17.1% to 4.4% of individuals post-COVID-19, especially in ICU survivors [21,31,33]. Neurocognitive parameter including immediate verbal memory and semantic verbal fluency were moderately impaired in 58.7% and severely impaired in 18.4% of post-COVID-19 patients [33]. More than half of the patients presented at least one stress-related symptom (anxiety, depression, and PTSD) [35] or neurocognitive impairment [33].

The associations between mental health symptoms and demographic characteristics were evaluated in most studies. Inconsistent findings were reported for the association between age and psychological symptoms: four studies found an inverse relationship [16,21,31,35,36], whereas three studies reported no association [4,31,33]. Greater psychological impact was observed in females post-COVID-19, with a 2.2- to 2.5-fold higher odds of developing psychiatric morbidity [21,29,33,36]. Comorbidities (arterial hypertension, coronary artery disease, and diabetes mellitus) were not related to a higher incidence of mental health problems [31,36,37]. Previous psychiatric disorders were associated with increased severity of post-COVID-19 mental health symptoms [35,36]. However, even individuals without previously diagnosed mental health morbidity (74%) reported anxiety and depression symptoms post-COVID-19 [21]. One study reported a significant direct relationship between symptoms of depression and baseline immune responses [38], and inverse associations were found elsewhere with lung function parameters (forced vital capacity [FVC]) and post-discharge respiratory symptoms [4,29].

## 4. Discussion

This review highlights the presence of several physical and mental health problems post-COVID-19 after follow-up periods of up to 3 months. Among the physical health problems, fatigue was the most common musculoskeletal symptom reported post-COVID-19. Long-lasting fatigue has been reported previously after other viral infections [39–42]. Several studies have investigated the associations between fatigue and disease severity, gender, age, comorbidity, and a pre-existing diagnosis of depression and/or anxiety [15,16,26,27,30]. Greater fatigue and pain at follow-up were reported, apparently, by patients who had experienced severe SARS-CoV-2 infection [16,21,26]. However, inconsistent findings were reported in studies that evaluated the association between disease severity and fatigue; differences among studies maybe due to the severity criteria used for COVID-19 and to different admission or discharge protocols [16,21,24–26]. Fig. 1. PRISMA flowchart for the literature review.

tended to experience fatigue to a greater extent compared to men [21,24,27]. This is consistent with the higher rate of chronic fatigue syndrome reported in females, which has been linked to stress-related factors [43].

Physical health declines were found mostly with the physical role functioning, mobility and usual activity [16,29,34], which are related to participation in work and regular daily activities [44]. In addition, reduced physical capacity was evident as lower 6MWT results post-COVID-19 compared to the average value of >650 m in healthy adults [45], with no decrease in oxygen saturation during testing [12–15,46]. These findings suggest a role for factors other than pulmonary dysfunction in reduced physical capacity. Previously, declines in physical activity were reported in individuals who recovered from SARS and experienced restrictions in activities of daily living and work participation [47,48]. Physical performance should ideally be assessed in a way that includes both functional capacity measurements (e.g., 6MWT, STS), and muscle strength, to gain better insights that can be used in clinical practice. However, only one study evaluated muscle strength at 3-months' post-COVID-19 follow-up, and reported that 18% of individuals admitted to the ICU had acquired weakness [49]. Muscle weakness and acute sarcopenia have been observed in COVID-19 survivors [8,50]. Among individuals infected with the coronavirus, Paneroni et al. found quadriceps weakness in 86% and biceps brachialis

weakness in 73% at hospital discharge [50]. This finding further highlights the importance of evaluating muscle strength at follow-up [51,52], because it is associated with poor functional outcomes and long-term disability [51]. Functional decline and lower physical capacity were evident in both hospitalized (ward and ICU) and non-hospitalized patients at follow-up periods of 1 and 3 months post-COVID-19. Accordingly, physical inactivity as a consequence of quarantine, social distancing and isolation may also be a source of reduced physical capacity and function in persons who are recovering from COVID-19.

Most studies included in the present review reported psychological and neuropsychological issues (anxiety and depression, PTSD, sleep and cognition problems) post-COVID-19, even in individuals with no previously diagnosed mental health problems. This is consistent with the findings of two metaanalyses of survivors of previous coronavirus epidemics [9,53], which found that one third of patients experienced at least one psychological impairment (PTSD, depression, and anxiety) more than 6 months post-discharge [9]. The prevalence of mental health symptoms varies widely among studies, which may be due to differences in the instruments used to measure these outcomes, and to differences among countries in the impact of cultural or spiritual beliefs in efforts to cope with the psychological effect of coronavirus disease [54,55]. Some studies reported an association between anxiety, depression and PTSD

with physical symptoms [15,21,24,31]. Wang et al. proposed a chain model to describe the link between physical symptoms and mental health via the need for health information and perceived impact of pandemic mediators. Excessive conflicting health information regarding the physical symptoms of COVID-19 might exaggerate the perceived impact of the pandemic, thus predisposing individuals to a higher risk of anxiety, depression and stress [55].

Sleep problems were another prominent mental health problem post-COVID-19, especially insomnia, which was observed in both acute and chronic stages of the disease [16,19,27,56]. Physical and psychological stress in the acute stage of the infection can trigger physiological mechanisms that stimulate pro-inflammatory cytokine release, which in turn can interfere with metabolic and cardiovascular functions related to sleep [56]. McNally et al. (2015) suggested that sleep problems may impair both emotional and attentional regulation, and cause irritability and concentration problems [57]. Other studies suggested that sleep problems were a central complication perceived among COVID-19 survivors [29,37].

Mental health symptoms were more frequent among females [4,21,29,35]. This may be due to the greater susceptibility of women to stressors, or more likely the higher rate of reporting psychological symptoms [58,59]. Depression, PTSD, and cognitive problems (concentration and short-term memory impairment) were more frequent among ICU survivors than ward patients [21,60]. In addition, post-COVID-19 symptoms of cough, fatigue, and chest distress were risk factors for PTSD [60]. The symptoms of PTSD are a well-recognized component of post-ICU syndrome caused by a variety of factors including fear of dying, invasive treatment, pain, delirium, inability to communicate, weakness, immobility, sensory problems, and sleep deprivation [61]. Stress-related symptoms (anxiety, depression, and PTSD) and delirium were associated with an approximately 4-fold increase in the odds of developing neurocognitive impairment [33], and neurocognitive impairments were related with a 4.5-fold increase in the odds of psychiatric morbidity (anxiety, depression, and PTSD) [33]. Considered together, neuropsychological factors may increase neurocognitive impairments [33,38] and even mortality [62], so it is important to consider psychiatric rehabilitation for post-COVID-19 survivors, and measures to strengthen protective factors such as social support that act as stress-buffering mechanisms.

The post-COVID-19 symptoms studied thus far appear to resemble chronic fatigue syndrome, which has been reported after other viral infection [63]. The diagnosis of this syndrome requires the concurrent presence of at least four symptoms among muscle pain, joint pain, post-exertional fatigue, cognitive problems (memory and concentration), and sleep problems, for more than 6 months [64]. Although the symptoms related to this syndrome are present post-COVID-19, the studies included in the present review were all related to follow-up periods shorter than 6 months.

Behavioral psychotherapy treatments such as cognitive behavioral therapy (CBT) are recommended for chronic fatigue syndrome [65]. Nevertheless, face-to-face CBT is a time-intensive treatment, and is not applicable during the pandemic because of government restrictions that require social distancing and quarantines. Modern modes of digital communication can, however, enable efficient support in the form of rehabilitation services provided via information and communication technologies, and comprising prevention, assessment, intervention, supervision, education and consultation during the pandemic [66–68]. The advantages of internet consultations and smart phone applications for telehealth (telerehabilitation and telepsychiatry) are that they can minimize viral transmission from face-to-face therapy, reduce travel time and costs, minimize the need to schedule appointments, and improve treatment accessibility [67–69]. Internet CBT (I-CBT) has been reported to be an effective and efficient treatment for psychiatric problems and musculoskeletal symptoms [70,71]. Therefore, telehealth could be considered as a follow-up treatment for post-COVID-19 patients in efforts to prevent long-lasting physical and mental health

complications.

#### 4.1. Limitations

According to the WHO description of health, only physical and mental health dimensions were reviewed in this article, therefore other dimensions such as post-COVID-19 social health consequences and its related factors were not considered in this study. This review was restricted to only English language studies. In addition, measurement bias may have influenced the results of studies that used self-reported questionnaires with single-item questions and used telephone contact to collect information at follow-up.

#### 5. Conclusion

This scoping review highlights the persistence, for up to 3 months post-COVID-19, of physical and mental health problems that can reduce quality of life. Early screening and comprehensive rehabilitation planning may be required to effectively prevent and manage post-COVID-19 complications. This approach could reduce economic and clinical health consequences, and prevent long-term disability.

#### Funding

This research did not receive any specific grant from funding agencies in the public, commercial, or not-for-profit sectors.

#### Authors' contributions

All authors (S.S., M.T., N.Z., I.E., S.A.A.) participated in the conceptualization of this study. M.T., S.A.A., and S.S participated in the methodology and analysis. S.S., M.T., N.Z., and S.A.A. contributed to the writing. S.S. and M.T. were the main contributors to manuscript writing. All authors (S.S., M.T., N.Z., I.E. and S.A.A.) took part in manuscript revision, and all read and agreed to the published version of the manuscript.

#### Declaration of Competing Interest

The authors have no competing interests to report.

#### Acknowledgements

We thank K. Shashok (AuthorAID in the Eastern Mediterranean) for improving the use of English in the manuscript.
