Purpose: Although often performed using a variety of reconstructive techniques and strategies, no clinically significant differences presently exist between the approaches available for isolated PCL reconstructions. Given the operatively challenging nature of these procedures, there lies a potentially increased risk of postoperative complications and healthcare expenditures. Our investigation sought to identify patient and surgical risk factors associated with prolonged hospital stays following isolated PCL reconstruction and determine the incidence of 30-day complications after PCL reconstruction using the American College of Surgeons National Surgical Quality Improvement Program (ACS-NSQIP) database.

Method: Patients undergoing isolated PCL reconstructions between 2005 and 2016 were identified in the American College of Surgeons National Surgical Quality Improvement Program (NSQIP) database using Current Procedural Terminology codes. Baseline patient and operative characteristics were evaluated as possible risk factors for overnight hospital admissions following PCL reconstruction and analyzed using multivariate analyses.

Results: A total of 249 patients were identified. Multivariate analyses demonstrated that increased operative duration >120 mins (OR 5.04, CI 2.44–10.40; p <0.001) was associated with an increased risk of overnight hospital stay. Major complications occurred in 0.4% (N=1), and minor complications occurred in 0.8% (N=2) with overall complications occurring in 1.2% (N=3) of all patients. Wound dehiscence was the only major complication while superficial surgical site infection and deep vein thrombosis were the only minor complications. 34.1% (N=85) of patients required an overnight hospital stay postoperatively.

Conclusion: Surgical duration >120 mins carried an increased risk of overnight hospital stay after isolated PCL reconstructions. As there are presently minimal significant clinical differences between current PCL reconstruction techniques, improved surgeon familiarity and comfort with a single technique is recommended to decrease operative time and avoid prolonged hospital stays and healthcare expenditures.

Level of evidence: III, retrospective comparative study.

Introduction

Knee arthroscopy is one of the most common surgical procedures in the United States with meniscectomy, meniscal repair and cruciate ligament reconstruction composing the majority.¹ With otherwise low rates of associated complications and a rising incidence of arthroscopic surgeries performed among patients of all ages, there has also been a concomitant increase in the proportion of procedures

performed as outpatients with <1% of arthroscopies performed in an inpatient setting.^{1,2} An isolated PCL rupture is a relatively uncommon injury, as tears of the PCL are often associated with concurrent knee pathology such as anterior cruciate ligament (ACL), medial collateral ligament or posterolateral corner injuries.^{3,4} In a review of 222 acute knee injuries, Fanelli et al found that 38.3% involved PCL-related injuries, but only 3.5% were isolated PCL injuries. However, other investigations have studied cohorts with isolated PCL ruptures in up to 18% of patients, and comprising nearly 2% of all American high school knee injuries.⁵⁻⁷

The PCL was classically believed to be composed of independently functioning posteromedial and anterolateral bundles with the latter preventing posterior tibial translation in flexion and the posteromedial bundle more active in extension.^{8,9} However, more recent biomechanical analyses now suggest more synergistic actions of the two bundles as a result of their anatomical and spatial attachments about the femur and tibia.¹⁰⁻¹³ Operative management of PCL ruptures is indicated in the setting of concomitant injury to the surrounding collateral ligaments, ACL or meniscus with nonoperative management recommended for isolated and lower severity injuries. The argument for nonoperative management of isolated ruptures is based on the purported intrinsic healing potential of the PCL, although concerns remain on the ligament healing in a lax or attenuated position.¹⁴⁻¹⁶ Despite good subjective functional scores and evidence of healing on MRI in the acute postinjury period for conservatively managed isolated PCL tears, less than satisfactory objective scores have been reported.¹⁴⁻¹⁹ Additionally, there has been evidence of increased radiographic progression of osteoarthritis and decreased functional outcomes in isolated PCL tears with increasing time from injury, specifically found in 23% of patients at 7 years of follow up, and 41% at 14 years of follow-up.¹⁷⁻¹⁹ Several strategies currently exist for PCL reconstruction from single-bundle or double – bundle reconstructions to transtibial and tibial inlay tibial graft fixation strategies however as it stands, no clinically significant differences in outcomes have been uncovered.²⁰⁻²⁴

Thus, consideration of operative management in select patients has become a topic of discussion; however, given the relatively technically challenging aspects of PCL reconstruction compared to its corollary in anterior cruciate ligament reconstructions, therein lies the potential for increased healthcare expenditures and complications from PCL reconstruction if the appropriate risk stratification or degree of

surgical preparation is not performed. To date, most complications with PCL injuries, either isolated or in the setting of associated injuries, are related to residual posterior laxity,^{21,25,26} popliteal artery laceration or occlusion,^{27,28} osteonecrosis of the medial femoral condyle²⁹ proximal tibial fracture³⁰ heterotopic ossification in the posterior capsule and decreased knee flexion.^{5,31} However, given the relatively low rate of reconstruction, most of these complications have been restricted to case reports or small series without any definitive reports on an overall incidence of complications.³² The American College of Surgeons National Surgical Quality Improvement Program (ACS-NSQIP) database has previously been applied to examine complications in a multitude of orthopedic procedures^{2,33-37} however, to date, we are unaware of any study that has analyzed the prolonged length of stay after isolated PCL reconstructions.

The aim of this study was to identify patient and surgeon-related risk factors associated with prolonged hospital stays following isolated PCL reconstruction. A secondary aim was to determine the incidence of 30-day complications after PCL reconstruction using the ACS-NSQIP database. We hypothesized that increased body mass index and operative time would increase the risk of prolonged postoperative hospital stays. We suspected obesity and prolonged surgical duration would predispose patients to an increased risk of perioperative complications thus requiring extended postoperative monitoring and a prolonged hospital stay.

Materials And Methods

This was a retrospective study using the ACS – NSQIP database. This large, multicenter registry contains prospectively collected data on patients undergoing surgery at over 400 hospitals around the United States. Data is collected by trained surgical clinical reviewers who follow patients' medical charts, collecting demographics, comorbidities, intraoperative variables, and 30-day postoperative major and minor complications based on specified criteria. As such, the NSQIP is a high-quality, accurate database for studying preoperative complications³⁸⁻⁴¹ and has been widely used to investigate complications of orthopedic procedures.^{33,34,36,38} This database is helpful to our research question because the large sample size provides us with the ability to document rates and risk factors, for relatively rare perioperative complications in less common procedures such as isolated PCL reconstructions. Access to this database was obtained by placing an electronic request through the ACS NSQIP website, and thus

institutional review board approval was not required to query this publicly accessible de-identified database.

Patient Selection

The database was surveyed of all cases with the Current Procedural Terminology (CPT) code 29889 (arthroscopically aided posterior cruciate ligament repair/augmentation or reconstruction) and excluded cases with the following primary/concurrent CPT codes: 29888 (arthroscopically aided anterior cruciate ligament repair/augmentation or reconstruction), 27405 (repair of torn collateral ligament or capsule), 27427 (extra-articular ligamentous reconstruction or augmentation), 27428 (open, extra-articular ligamentous reconstruction or augmentation) and 27407 (repair of torn cruciate ligament or capsule) to identify all isolated, elective PCL reconstructions within the database from 2005 to 2016. Those with missing demographic information such as age, height, weight, or sex were excluded from this study. In total, 207 of the 456 patients with a CPT of 29889 met one or more of the exclusion criteria and were removed from the investigation, most commonly for concurrent ligamentous injury (Figure 1).

Data Collection

Complications were divided into major and minor categories similar to the manner performed in prior literature.^{34,38} An overall complication rate, including both major and minor complications, was also included. Patient and surgical characteristics were defined by the ACS and were included in the NSQIP database. Demographic information including age and gender was assessed. Variables that were also analyzed include body mass index (BMI; calculated from patient height and weight, categorized according to the World Health Organization classifications)⁴² American Society of Anesthesiologists (ASA) classifications, and comorbidities including history of hypertension, diabetes mellitus, tobacco use, and chronic obstructive pulmonary disease (COPD). American Society of Anesthesiology classification was analyzed as a dichotomous value to differentiate the effects of mild versus severe systemic disease on prolonged hospital stay.⁴³ The complications that were assessed are presented in Table 1. The number of patients who required post-procedure overnight hospital stay ≥ 1 day was also determined.

Statistical Analysis

Statistical analysis was performed using SPSS version 23 (IBM, Armonk, NY). The rates of perioperative complications, readmissions and overnight hospital stays were compared with

χ^2 tests. A multivariate logistic regression analysis with an overnight length of hospital stay ≥ 1 day as an outcome variable and baseline patient and operative characteristics as covariates was performed. Regression analysis was performed to identify independent risk factors for overnight hospital stays. A statistically significant *p*-value was defined as <0.05 . Given the use of multiple statistical comparisons within the analysis, a Bonferroni correction was also performed.

Results

In total, 249 isolated PCL reconstruction cases were identified. Of the patients studied, 137 (55%) were <30 years of age, 168 (67.5%) had BMI < 30 , 43 (19.7%) were smokers and 77.9% were male (Table 2). The majority of cases (159, 63.9%) lasted more than 120 mins. Based on multivariate analyses, surgical duration lasting more than 120 mins (odds ratio [OR] = 5.04, CI 2.44–10.40; $p < 0.001$) was a statistically significant independent predictor of overnight hospital stay. Use of general anesthesia, BMI >30 , increased age >40 years, ASA classification of III or IV, and cigarette use were associated with overnight hospital stays postoperatively; however, these risk factors did not reach statistical significance (Table 3). In terms of complications, major perioperative events occurred in 1 (0.4%) patient and minor complications occurred in 2 (0.8%) patients. Minor complications included wound dehiscence ($n = 1$, 0.4%), superficial surgical site infection ($n = 1$, 0.4%) and symptomatic deep vein thrombosis requiring treatment ($n = 1$, 0.4%). Overall, 85 (34.1%) patients remained in the hospital overnight postoperatively.

Discussion

This study used a large, prospectively collected and multi-institutional registry, to identify patient and surgical risk factors associated with prolonged hospital stays following isolated PCL reconstruction. Overall, 34.1% of patients remained in the hospital for at least one night postoperatively. Multivariate analyses subsequently found prolonged operative time >120 mins to be an independent risk factor for postoperative overnight hospital admissions following PCL reconstruction. In addition, we found the overall rate of complications after PCL reconstruction was found to be 1.2%.

Posterior cruciate ligament reconstruction can be a technically challenging endeavor as the risk of serious and limb or life-threatening injury is a legitimate concern. These considerations could play a role in increasing operative time if the surgeon is unfamiliar with such a

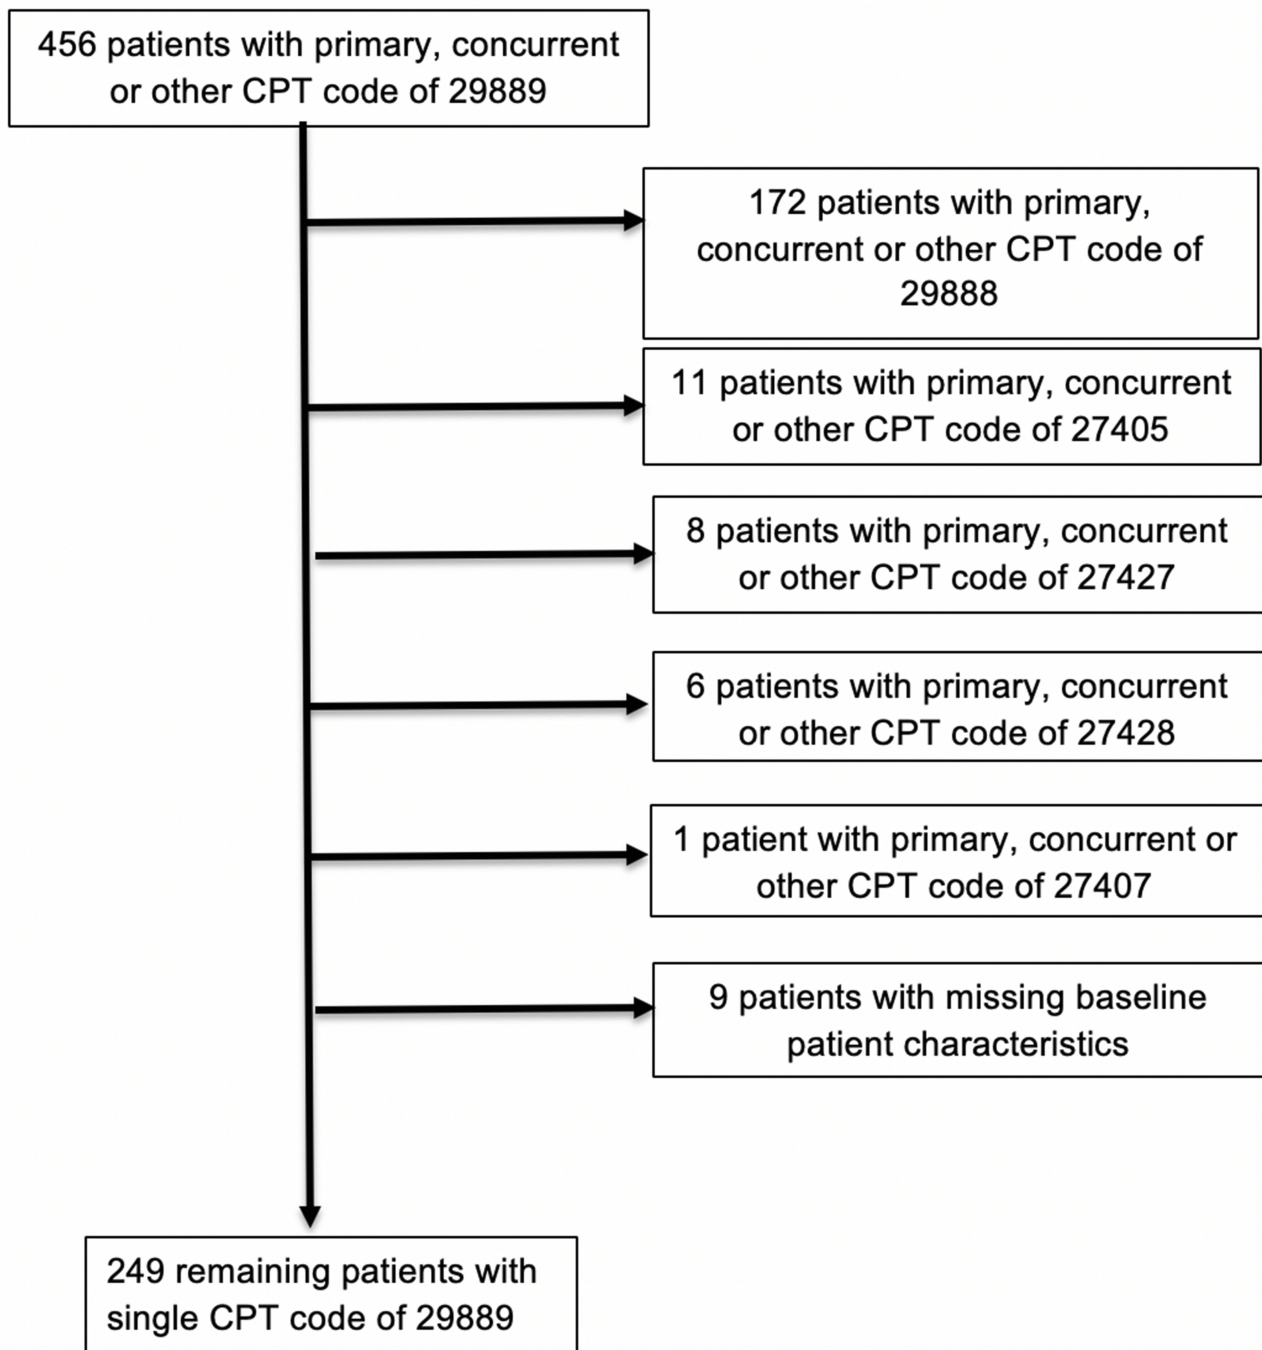

Figure 1 STROBE diagram of included and excluded cases of posterior cruciate ligament reconstruction [29889 = arthroscopically aided posterior cruciate ligament augmentation or reconstruction, 29888 = arthroscopically aided anterior cruciate ligament repair/augmentation or reconstruction, 27405 = repair of torn collateral ligament or capsule, 27427 = extra-articular ligamentous reconstruction (augmentation), 27428 = open, extra-articular ligamentous reconstruction (augmentation), 27407 = repair of torn cruciate ligament or capsule].

procedure. Cadaveric studies note, on average, 29.1 mm separating the mid-PCL from the popliteal artery and 9.7 mm between the proximal PCL fovea and the popliteal artery.⁴⁴ The degree of knee flexion intraoperatively can further influence this anatomic relationship as greater flexion increases the distance between the tibial insertion

of the PCL and the popliteal artery.⁴⁵ Laceration to the popliteal artery can occur with tibial tunnel drilling, yet similar injury is also possible during posteromedial portal creation or following manipulation of the posterior capsule.³² Although several techniques have been suggested to manage such concerns, such as creating safety

Table 1 Major And Minor Perioperative Complications Analyzed Within NSQIP Database

Major Complications		Minor Complications	
Death	Unplanned re-intubation	Superficial surgical infection	Urinary tract infection

much to be said about the level of surgeon comfort when indicating and performing these procedures. For example, the transtibial technique is known to be subject to the potential “killer turn” on the posterior aspect of the proximal tibia that can lead to graft abrasion from the sharp graft angulation at the intra-articular portion of the tibial tunnel.⁴⁸ As a result, the inlay technique was proposed to avoid this sharp bending angle and potential graft injury.⁴⁹ Despite the proposed improvements in surgical ease, there have been no clinically important differences in Tegner or Lysholm scores, nor differences in residual laxity.⁵⁰ Furthermore, when comparing single bundle and double-bundle reconstructions, Qi et al’s systematic review by Qi et al found no clear differences in clinical outcomes.⁵¹ More recently, Chahla sought to investigate differences in outcomes between double and single-bundle reconstructions 2 years postoperatively. Although both procedures led to an increased patient-reported outcomes and knee stability, double-bundle reconstruction showed improved posterior stability and International Knee Documentation Committee (IKDC) Scores. Yet, there were no other significant differences across other patient-reported outcomes.⁵² As with most procedures, a learning curve exists before which a surgeon can become facile with a given procedure. Within PCL reconstructions, a variety of procedures and techniques exist with similar functional and objective outcomes however varying levels of difficulty depending on surgeon familiarity. This inference cannot be definitively proven from our study; however, deeper investigation is merited to elucidate if there is a connection between overnight hospital stay in PCL reconstructions, operative duration and surgeon experience.

Under the growing quality-based reimbursement model within orthopedic surgery, physicians must become more cognizant of modifiable risk factors that can reduce adverse outcomes such as increased hospital length of stay for traditionally outpatient procedures.^{53,54} Across more recent arthroscopy literature, increasing operative time has been associated with increased healthcare utilization in the form of increased risk of readmissions after elective shoulder arthroscopy, and an increased risk of adverse events, extended the length of stay and readmissions in isolated ACL reconstruction.^{55–57} The findings of our investigation are similar to those of prior studies as the previously unreported variable of procedure length is identified as a factor that may be used for risk stratification in outpatient PCL reconstruction. As there is no clear consensus, at this time, on the overarching clinical and objective benefits between many of the current reconstruction

strategies presently available, as surgeons prepare for these cases, the focus should be on decreasing operative time by using more familiar techniques in order to reduce the risk of unexpected health expenditures. Although there is paucity of literature on the subject, surgeon comfort level and the concept of a learning curve associated with PCL reconstruction is a valuable area of interest that could further explain our findings and guide surgeons as they look to surgically manage PCL injuries.

Limitations

There are several limitations to our investigation. The ACS-NSQIP database lacks qualitative postoperative complication data and thus we are unable to identify specific causes behind the reported complications and exact reasons for why patients remained admitted postoperatively. Despite a large number of institutions contributing to the ACS-NSQIP database, it does not capture data from independent outpatient surgical centers. As such, we are unable to generalize our findings to PCL reconstructions performed in surgery centers. In addition, the database lacks orthopedic specific data of such as graft choice, operative indications, the selection of single or double-bundle reconstruction, DVT prophylaxis, postoperative weight-bearing status, pain scores, postoperative range of motion restrictions, patient-reported outcome scores, comparisons between preoperative and postoperative physical examination or symptom scores, and outcomes of interest following PCL reconstruction such as residual laxity or strength. Due to the relative rarity of isolated PCL reconstructions, our sample size may have limited our ability to identify statistically significant associations between patient and surgeon-related risk factors and adverse outcomes. Furthermore, although no prior study has reported on the incidence of complications after isolated PCL reconstruction, the relatively low incidence of complications and operative cases found amongst the cohort studied within the NSQIP database may have precluded further analyses. A prior investigation on anterior cruciate ligament reconstruction used the same database and reported a complication rate of 1.34% in the early postoperative period across 4933 patients.³⁸ In comparison, our study yielded a much smaller study sample of 249 patients but noted a 1.2% incidence of complications. Given the large differences in sample size, we would caution making any definitive claims on the incidence of complications following isolated PCL reconstruction and how it compares to other arthroscopic procedures. Similar to prior research utilizing

ACS-NSQIP while data are obtained through trained surgical clinical reviewers and subject to audits by the ACS⁵⁸ it may suffer from limitations common to large outcome databases including a lack of granularity to the data, as well as improper documentation or coding by individual physicians and medical groups contributing to the database. Although we mention discussions in the literature regarding the argument against nonoperative management, we are unable to make the claim that this procedure is being performed more frequently as no information is available on recent trends in isolated PCL reconstructions. Ultimately, larger prospective cohort or randomized controlled studies with long-term follow-up and homogenous patient populations are needed to better illustrate the complete complication profile, demographics and operative indications following isolated PCL reconstructions. The use of the ACS-NSQIP database allowed us to determine patient and surgical risk factors associated with prolonged hospital stays across a relatively uncommon arthroscopic procedure by using prospectively, and rigorously collected data obtained from a multitude of institutions. It is our hope that our findings will highlight patient and surgeon-specific factors that can increase the risk of further health-care expenditures for traditionally outpatient procedures.

Conclusion

Surgical duration >120 mins carried an increased risk of overnight hospital stay after isolated PCL reconstructions. As there are presently minimal significant clinical differences between current PCL reconstruction techniques, improved surgeon familiarity and comfort with a single technique is recommended to decrease operative time and avoid prolonged hospital stays and healthcare expenditures.

Therapeutics and Clinical Risk Management

Dovepress

Publish your work in this journal

Therapeutics and Clinical Risk Management is an international, peer-reviewed journal of clinical therapeutics and risk management, focusing on concise rapid reporting of clinical studies in all therapeutic areas, outcomes, safety, and programs for the effective, safe, and sustained use of medicines. This journal is indexed on PubMed Central, CAS,

EMBASE, Scopus and the Elsevier Bibliographic databases. The manuscript management system is completely online and includes a very quick and fair peer-review system, which is all easy to use. Visit <http://www.dovepress.com/testimonials.php> to read real quotes from published authors.
