**Summary** Reduced expression of the adhesion molecule E-cadherin has been associated with increased invasiveness and poorer survival in patients with bladder cancer. We have examined soluble E-cadherin (sE-cadherin) and total protein concentrations in urine from patients with bladder cancer ( $n = 34$ ), non-neoplastic benign urological diseases ( $n = 14$ ) and healthy controls ( $n = 21$ ) to determine their diagnostic and prognostic significance. Soluble E-cadherin concentrations of the cancer group were significantly higher ( $P < 0.001$ ) than those of the controls but the benign group was not significantly different from either the cancer group or the controls. When sE-cadherin concentrations were adjusted for creatinine, similar but more statistically significant results were obtained and the benign group was significantly elevated compared with the controls ( $P < 0.01$ ). No differences were apparent between the invasive (pT1–4) and non-invasive (pTa) cancers. Urinary total protein concentrations in the cancer group were significantly higher than the controls ( $P < 0.001$ ) and the benign group ( $P < 0.05$ ) although no difference was seen between the benign group and patients with non-invasive (pTa) cancer or between the benign group and controls. When expressed as the protein/creatinine index, results were similar but more statistically significant and a significant difference was seen between invasive and non-invasive cancers ( $P < 0.01$ ). Only the protein/creatinine index correlated significantly with stage of the tumour ( $P < 0.01$ ). It is concluded that urinary sE-cadherin measurements are of no greater value than urinary total protein.

**Keywords:** soluble adhesion molecules; E-cadherin; bladder; urine; cancer

Bladder cancer is the fourth most common cancer in men and the tenth in women, with approximately 12 500 new cases in the UK (Cancer Research Campaign Factsheet 9.1, 1997). Stage and grade as measures of the depth of invasion into the bladder wall and degree of differentiation of the tumour, respectively, are currently the most widely used indicators of prognosis. Other known adverse risk factors include the presence of multiple tumours at presentation (Parmar et al, 1989), the recurrence of tumours at 3 months post-cystoscopy (Reading et al, 1995) and p53 mutations (Esrig et al, 1994; Caliskan et al, 1997).

For patients presenting with superficial bladder cancer (pTa and pT1) the prognosis is good. Although recurrences occur in approximately 70% of patients, only 10–15% progress to muscle-invasive disease (Hudson and Catalona, 1996). However, there is a need for regular monitoring to identify patients at risk of recurrence or progression as early as possible so that appropriate therapy can be initiated promptly. To date, there are no established tumour markers available, although several have been investigated in preliminary studies with promising results in terms of diagnostic or prognostic use. These include bladder-tumour associated analyte (BTA; Sarosdy et al, 1995; D'Hallewin and Baert, 1996; Leyh et al, 1997), nuclear matrix protein 22 (NMP22; Soloway

et al, 1996), telomerase activity (Kinoshita et al, 1997; Yoshida et al, 1997), Ki-67 antigen and p53 protein expression (Tsuji et al, 1997), microsatellite analysis (Mao et al, 1996; Steiner et al, 1997) and matrix metalloproteinases, their inhibitors and activators (Gohji et al, 1998; Kanayama et al, 1998).

Cadherins are Ca<sup>2+</sup>-dependent homotypic adhesion molecules essential for maintaining intercellular adhesion (Takeichi, 1990). E-cadherin (120 kDa) is mainly involved in epithelial cell–cell interactions with loss being associated with increased invasiveness and decreased differentiation in a variety of malignancies including breast, prostate and gastric carcinoma (Takeichi, 1993). Decreased, heterogeneous or absent expression of membrane-associated E-cadherin has been reported in malignant bladder tumours, with abnormal expression correlating with increasing grade and invasiveness (Bringuier et al, 1993; Otto et al, 1994; Lipponen and Eskelinen, 1995; Ross et al, 1995; Syrigos et al, 1995) and associated with reduced survival (Bringuier et al, 1993; Syrigos et al, 1995). Similarly in patients with pTa or pT1 bladder tumours, abnormal expression of E-cadherin has been associated with more rapid progression and reduced survival (Otto et al, 1994; Lipponen and Eskelinen 1995).

Although changes in expression of E-cadherin may account for changes in cell invasiveness, additional mechanisms may also contribute to altered function of this adhesion molecule (Hiraguri et al, 1998). Point mutations in the calcium binding sites (Ozawa

et al, 1990; Kanai et al, 1994), loss of heterozygosity (Becker and Hofler, 1995), hypermethylation of the promoter region (Yoshuira et al, 1995), aberrant function of the catenins (Shimoyama et al, 1992) or increased shedding of E-cadherin from the cell membrane (Matsuura et al, 1992), have all been proposed as contributory mechanisms for impairment of adhesive function.

Soluble forms of several adhesion molecules have been identified (Gearing and Newman, 1993), and a soluble form of E-cadherin (sE-cadherin; 80 kDa) has been shown to be shed by the MCF-7 breast cancer line (Damsky et al, 1983). Proteolytic cleavage of E-cadherin from the cell surface may account for the soluble form (Matsuura et al, 1992), which has been found in serum (Katayama et al, 1994a; Griffiths et al, 1996) and in urine (Katayama et al, 1994b; Banks et al, 1995) with elevated levels in patients with a variety of cancers. Following the recent finding of elevated serum sE-cadherin concentrations in patients with bladder tumours (Griffiths et al, 1996), we have performed a preliminary cross-sectional study measuring urinary sE-cadherin levels in patients with bladder cancer, non-neoplastic conditions and healthy volunteers and compared these with urinary total protein levels to establish whether such measurements may be of use clinically for diagnostic or monitoring purposes.

## MATERIALS AND METHODS

Urine samples were collected over a period of several months from patients attending the urology ward for investigations prior to treatment. Details of the patient and control groups are provided in Table 1. Aprotinin was added (final concentration 100 KIU ml<sup>-1</sup>) and the samples were centrifuged at 1500 g for 10 min to remove cellular debris before being aliquoted and stored at -70°C until assayed. Additional samples were collected from healthy volunteers. Histological specimens were reviewed independently and

blindly by a single pathologist and all tumour sections were staged according to the TNM classification (Hermanek and Sobin, 1987) and graded according to the WHO criteria (Mostofi et al, 1973). The tumour stage and grade of the patients with bladder cancer are shown in Table 2. The benign group consisted of two patients with inflammatory conditions of the bladder, four with benign prostatic hypertrophy, two with kidney stones, one with moderate dysplasia and five were patients who had previously been treated for non-invasive malignancies but currently had normal biopsies.

Soluble E-cadherin concentrations were determined using a commercially available enzyme-linked immunosorbent assay (ELISA) according to the manufacturer's instructions (Takara Shuzo, Japan). This assay is based on the capture of sE-cadherin using a solid-phase adsorbed monoclonal antibody followed by subsequent detection using a labelled second monoclonal antibody to E-cadherin, with a detection limit of < 50 ng ml<sup>-1</sup>. Urinary protein concentrations were determined by standard automated analysis with a Bayer Axon analyser using pyrogallol red reagent (0.05 mM; Sigma, UK) with a timed end-point method and standardization against human albumin (Sigma). Creatinine concentrations in urine were measured by the Jaffe method (Rock et al, 1986) using the Bayer Axon analyser. Both sE-cadherin and total protein concentrations were adjusted for creatinine concentration and expressed as a sE-cadherin/creatinine index or protein/creatinine index, respectively, calculated as protein (g l<sup>-1</sup>) × 10 000 divided by creatinine (mmol l<sup>-1</sup>) with units of × 10 g μmol<sup>-1</sup> to be in accordance with previous studies (Dyson et al, 1992; Mitchell et al, 1993).

Urine samples from 12 controls and 21 of the patients with bladder tumours were analysed by Western blotting following electrophoresis on 8% sodium dodecyl sulphate (SDS) polyacrylamide gels under reducing conditions, as previously described (Banks et al, 1995).

## Statistical analysis

Statistical analysis was carried out using SPSS-PC (SPSS Inc, Illinois, USA). As the data were found to be non-normally distributed using the Shapiro-Wilks and K-S (Lilliefors) tests, the non-parametric Mann-Whitney test and Spearman's correlation were used. Differences were judged to be statistically significant if  $P < 0.05$ .

## RESULTS

A total of 69 samples were assayed. As the ages between the normal (healthy and benign controls) and malignant groups differed significantly ( $P < 0.05$ ), the relationship of the assayed parameters with age was examined but no correlations were found.

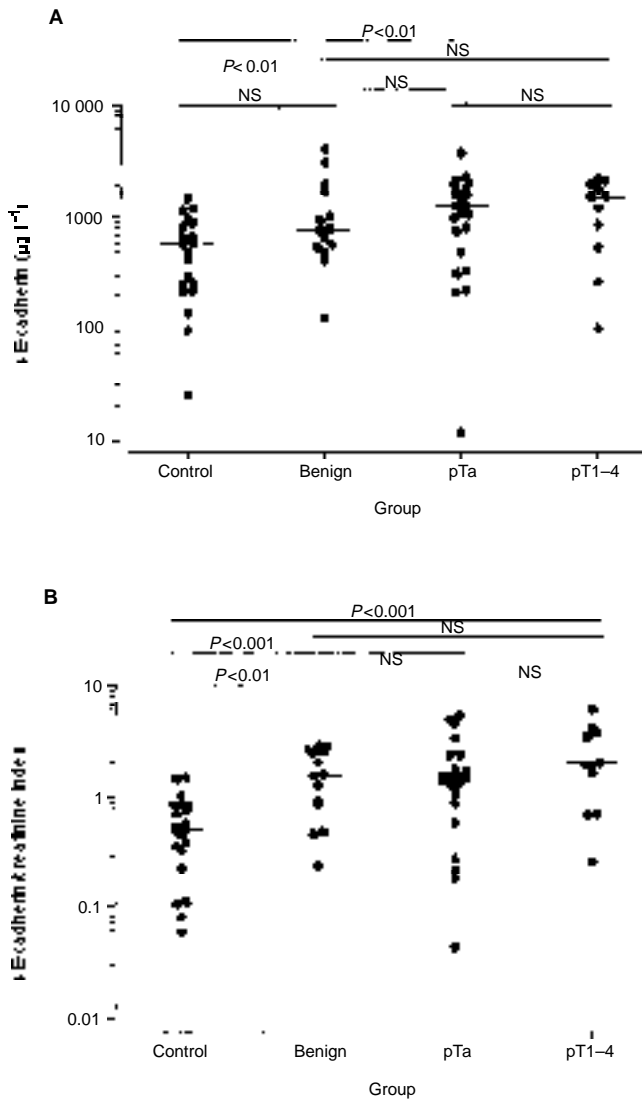

Considerable overlap was seen between the groups regarding urinary sE-cadherin concentrations (Figure 1A) with the only statistically significant differences being seen between the control (range 24.9–1437, median 582) and neoplastic group, whether the latter was examined as a whole (range 12–3813, median 1272.5) or subdivided into the non-invasive (pTa; range 12–3812, median 1284) and invasive (pT1–4; range 97.7–2327.2, median 1551) cancers ( $P < 0.001$ ,  $P < 0.01$ ,  $P < 0.01$  respectively). When adjusted for creatinine concentration (Figure 1B), the difference between the control (range 0.058–1.481, median 0.516) and neoplastic groups (whole: range 0.043–6.0, median 1.536; pTa: range 0.043–5.271, median 1.477; pT1–4: range 0.026–6.0,

**Figure 1** (A) Urinary sE-cadherin levels ( $\mu\text{g l}^{-1}$ ) and (B) urinary sE-cadherin/creatinine index versus patient group; — represents the median value

median 1.939) became more significant ( $P = 0.0001$ ,  $P < 0.001$  and  $P < 0.001$  respectively) and additionally a significant difference ( $P < 0.01$ ) was seen between the control (range 5.8–148.1, median 51.6) and benign group (range 24.1–282.6, median 157.3). However, there was no apparent difference between the benign group and patients with cancer, or between patients with non-invasive (pTa) or invasive disease (pT1–4).

When the urinary total protein concentrations were analysed (Figure 2A), considerable overlap between groups was again seen, but patients with tumours (range 0.03–6.38, median 0.255) had significantly higher concentrations than those of the control group (range 0.01–0.72, median 0.07) ( $P < 0.001$ ) or the benign group (range 0.02–7.75, median 0.085) ( $P < 0.05$ ). However, when the neoplastic group was subdivided into invasive (pT1–4) (range 0.04–6.38, median 0.4) and non-invasive (pTa) cases (range 0.02–2.19, median 0.22), only the protein concentrations of the invasive sub-group were significantly higher than those of the benign group ( $P < 0.05$ ). No significant difference was seen between the invasive and non-invasive groups or between the

**Figure 2** (A) Urinary total protein ( $\text{g l}^{-1}$ ) and (B) protein/creatinine index versus patient group; — represents the median value

benign and control groups. When the protein/creatinine index was used (Figure 2B), similar but more significant differences were seen between the groups (healthy controls: range 20.8–454.6, median 90.9; benign controls: range 27.8–10 616.4, median 113.2; neoplastic group: range 59.7–4524.8, median 263.6) and, in addition, a significant difference ( $P < 0.01$ ) was seen between

**Table 3** Numbers of urine samples with each form of sE-cadherin as detected by Western blotting

sE-cadherin	Normal controls (n = 12)	Cancer group (n = 21)							
		Grade			Stage				
		G1	G2	G3	pTa	pT1	pT2	pT3	pT4
No band	1	0	1	1	1	0	0	1	0
80 kDa only	8	1	9	5	11	1	0	2	1
80 and 65 kDa	3	0	1	3	2	1	0	1	0

non-invasive (range 59.7–4206.9, median 214.3) and invasive cancers (range 153.9–4524.8, median 776).

No significant correlation was found between sE-cadherin concentrations (absolute or following adjustment for creatinine) or total protein and tumour stage or grade. However, the protein/creatinine index correlated significantly with tumour stage ( $P < 0.01$ ) and just failed to reach a significant correlation with tumour grade ( $P < 0.06$ ).

A main sE-cadherin band of 80–85 kDa was detected by Western blotting (as shown previously; Banks et al, 1995) in 30 out of 33 samples (Table 3) with a further additional band of 65–70 kDa apparent in 20–25% of both the control and patient samples. No bands were detected in the blots incubated with an irrelevant primary antibody as a non-specific binding control.

## DISCUSSION

Loss or decreased expression of the adhesion molecule E-cadherin correlating with tumour progression has now been shown immunohistochemically in many tumour types (reviewed by Takeichi, 1993) illustrating the important role of this molecule in maintaining normal epithelial cohesion. Earlier studies showing the occurrence of a soluble form of this molecule in cell culture systems *in vitro* (Damsky et al, 1983) have led to the search for and subsequent finding of soluble forms in biological fluids *in vivo* with the hope that such a molecule may in some way reflect tumour progression and hence lend itself to being a tumour marker. Following our previous observations of the presence of sE-cadherin in urine (Banks et al, 1995), we have now demonstrated that urinary sE-cadherin concentrations are significantly increased in bladder cancer patients compared to normal controls, whether expressed as an absolute concentration or following adjustment for creatinine concentration.

The exact mechanism of production of the soluble form of E-cadherin is not known. Alternatively spliced forms of some adhesion molecules such as P-selectin have been described which lack the transmembrane region (Gearing and Newman, 1993) but similarly generated transcripts have not been described as yet for soluble E-cadherin. Proteolytic cleavage is also known to be important in the generation of many soluble molecules and studies have shown such a mechanism can occur for soluble E-cadherin (Damsky et al, 1983; Katayama et al, 1994a) with the intact molecule of 110–120 kDa being proteolytically digested to yield an 80 kDa molecule as found in this study. This may occur to a limited extent during normal cellular turnover but would be expected to be increased in conditions where protease release is enhanced. As such, significant differences in sE-cadherin concentrations would be expected between the non-invasive and invasive subgroups. The apparent absence of any such difference may be due to the relatively small number of patients in this study, although considerable overlap is seen between the groups. Given the overlap between groups, and the lack of correlation with stage or grade, the clinical use is likely to be limited.

The existence of two soluble forms of E-cadherin in urine (65 kDa and 80 kDa) as detected by Western blotting was described in our original study (Banks et al, 1995) and confirmed in this study. The significance of the two forms is unclear with the simultaneous presence of both forms being seen in 20–25% of both controls and patients with bladder cancer. It is likely that proteolysis accounts for the two fragments of the protein but this

needs to be confirmed. The proteolysis is unlikely to have occurred *in vitro* as samples were collected containing protease inhibitors. It is also not known whether both these fragments are detected by the immunoassay used in this study which may result in underestimation of the sE-cadherin concentration in some samples. Soluble E-cadherin molecules with electrophoretic mobilities ranging from 75 to 85 kDa have been reported before in urine samples from patients with benign and malignant conditions (Katayama et al, 1994b).

The only other study which has examined sE-cadherin concentrations in patients with bladder cancer analysed serum samples from patients at presentation (Griffiths et al, 1996) and found significantly higher concentrations than controls in patients with high-grade tumours or muscle-invasive disease. These are similar to our findings using urine samples, although we detected a significant difference between the control and non-invasive groups. No apparent difference was seen between the non-invasive and invasive groups in either study and neither did serum sE-cadherin concentration correlate with abnormal E-cadherin expression on the surface of bladder tumours (Griffiths et al, 1996). This does not support an increased rate of shedding as being the sole mechanism for the decreased cellular expression in cancer.

Increased urinary protein excretion is a relatively common finding in patients with bladder cancer, with concentration being related to tumour size but not grade and a significant reduction being seen following successful treatment (Johansson, 1975; Johansson and Kistner, 1975; Hemmingsen et al, 1981). Qualitative studies have shown the increased concentration of a number of proteins including IgG, IgA, transferrin,  $\alpha_1$ -acid glycoprotein, haptoglobin, fibrinogen,  $\alpha_1$ -antitrypsin and  $\alpha_2$ -macroglobulin, a similar profile also being seen in infection (Johansson, 1975; Johansson and Kistner, 1975; O'Brien et al, 1980, 1981). The finding of a predominantly glomerular proteinuria decreasing, but not returning to normal, after successful treatment or urinary diversion, particularly in higher grade tumours where it may be of predictive value (Hemmingsen et al, 1981), has been proposed to be associated with the finding of glomerular deposition of antigen-antibody complexes in urothelial malignancies (Jones et al, 1975). Additionally, some proteins may be present due to leakage from the plasma, possibly caused by tumour neovascularization, invasion or an inflammatory response, or alternatively may be derived from the tumour itself as a result of increased cellular turnover. Examining total protein concentration provides limited information due to its lack of tumour-specificity, being elevated, for example, by infection. However, in this study at least, total protein appears to be superior to sE-cadherin as a 'marker' in bladder cancer and is considerably cheaper to assay. Although the protein/creatinine ratio is significantly different between groups, the considerable overlap prohibits its use diagnostically. It is possible that longitudinal measurements may be of use on an individual patient basis as an initial follow-up screen but additional factors producing an increase in protein concentrations such as infection would need to be excluded.

Expressing the urinary results following adjustment for creatinine concentration is probably the more valid reflection of overall sE-cadherin or total protein release as it takes into account the variations in the renal function and hydration state of patients and when evaluated for total protein measurements has been shown to allow the use of single sample analysis as an adequate substitute

for 24-h collection and measurement (Dyson et al, 1992; Mitchell et al, 1993). Whether there is a diurnal variation on sE-cadherin concentration, and thus an optimal time for sample collection other than the mid-morning samples used in this study, was not established. The presence of intercurrent renal disease should also be taken into account due to its effects on the creatinine and hence the creatinine adjusted parameters. In this study, none of our patients were being treated for renal disease although six patients had mildly elevated serum creatinine concentrations.

Although significant differences were found between normal control and malignant groups, the overlap in the values between these groups and also those of the benign group indicate that measurement of urinary sE-cadherin concentrations alone could not be used as the basis for screening for malignant disease. However, in the light of the earlier results showing patients at risk of early relapse had significantly elevated levels of serum sE-cadherin at presentation (Griffiths et al, 1996), this should be explored further in a longitudinal study using both serum and urine samples. In addition, the use of urinary total protein should be explored further as it appears to be superior to sE-cadherin in its discriminatory capacity and would be more cost effective.
