Background: Non-alcoholic fatty liver disease (NAFLD) is increasingly recognized as a cause of chronic liver disease, often resulting in liver cirrhosis, portal hypertension, and hepatocellular carcinoma damaging outcomes. Alanine transaminase (ALT) and aspartate aminotransferase (AST) are indicators of hepatocellular injury. Several studies have demonstrated that high ALT levels are correlated with higher nonalcoholic steatohepatitis (NASH) risk. The aim was to determine the correlation of serum alanine aminotransferase and aspartate transaminase with liver stiffness in Vietnamese patients with NAFLD.

Patients and Methods: The study included 18 to 80 years old patients diagnosed with fatty liver on ultrasound at the University of Medical Center (UMC) liver clinic. Liver stiffness was measured using transient elastography. The histopathological, demographic, and laboratory data of the participants were also collected. The baseline and clinical characteristics of NAFLD patients were stratified by serum ALT levels.

Results: There were 138 NAFLD patients, including 82 men (59.4%) and 56 women (40.6%) (mean \pm SD age of 41 ± 11 years). Liver fibrosis (F0) between the two groups showed no significant difference ($p = 0.469$). Similarly, no difference was found in the mild fibrosis level (F2) of the two groups of patients ($p = 0.371$). ALT level was significantly higher in NAFLD patients with advanced fibrosis (F3, F4) (3.2% vs 15.9%, $p = 0.0013$; 3.2% vs 13.2%, $p = 0.0047$, respectively). NAFLD patients with mild to moderate fibrosis (F1-F2) were detected at 59 U/L cut-off value with 67% sensitivity and 51% specificity. However, severe fibrosis and/or cirrhosis patients (F3-F4) had a cut-off value of 81 U/L with 53% sensitivity and 67% specificity in patients.

Conclusion: Using ALT level as a marker for severe NAFLD would consider high-risk patients as mild cases, even though there is still the risk of progressive and severe hepatic disease. Our study underlines the small contribution of ALT as an independent factor for detecting NAFLD severity.

Keywords: alanine transaminase, aspartate aminotransferase, body mass index, fibrosis, NAFLD, triglyceride

Introduction

As non-alcoholic fatty liver disease (NAFLD) is a common disorder worldwide with 10–30% prevalence in various countries.¹ NAFLD is increasingly recognized as a cause of chronic liver disease that often results in liver cirrhosis, portal hypertension, and hepatocellular carcinoma damaging outcomes.^{1,2} NAFLD is

commonly associated with diabetes and is an essential feature of metabolic syndromes and insulin resistance.^{1,3,4} NAFLD severity spectrum varies. It ranges from mild symptoms to different inflammation degrees, nonalcoholic steatohepatitis (NASH), or a severe form of decompensated liver cirrhosis, which occurs in few patients.² NAFLD diagnosis is based on a patient's clinical history, laboratory analysis, imaging, and histology. Hepatic steatosis on abdominal imaging may be sufficient for NAFLD diagnosis. However, liver fibrosis assessment is essential for predicting chronic liver disease forms, prognosis, and outcomes. Liver biopsy is the gold standard for assessing liver fibrosis, but due to potentially life-threatening complications, it is performed as a last resort.⁵ Transient elastography (TE) is an ultrasound-based method that can simultaneously evaluate hepatic steatosis and liver fibrosis by measuring the controlled attenuation parameter (CAP) and liver stiffness (LS). Studies have shown that LS strongly correlated with the liver fibrosis stage assessed by liver biopsy.^{3,6} Thus, TE is more accurate than biomarkers or scoring systems for detecting significant liver fibrosis and cirrhosis.⁷

Alanine transaminase (ALT) and aspartate aminotransferase (AST) are indicators of hepatocellular injury. Several studies have demonstrated that high ALT levels are correlated with a higher risk of NASH.^{4,8} Some studies have shown that patients with a normal ALT level may also have histological features of NASH and are at risk of disease progression.^{9,10} Additionally, some recent studies have introduced a new ALT upper limit for a healthy individual, which is ≤ 40 U/L for both sexes. Elevated ALT levels are sometimes associated with an underlying NAFLD.¹¹ Therefore, this study investigated the correlation of liver stiffness measurement with serum alanine aminotransferase and aspartate transaminase as a screening tool for disease progression in high-risk patients; thereby reducing liver biopsies need.

Patients and Methods

Study Population and Data Collection

The study population included patients diagnosed with NAFLD based on abdominal ultrasound examination and serum liver enzyme testing performed at the University of Medical Center (UMC) liver clinic. Patients were aged between 18 to 80 years diagnosed with fatty liver on ultrasound (hyperechoic liver where the liver's echotexture was brighter than the kidney and had blurred

vascular margins and deep attenuation of ultrasound signal). NAFLD was diagnosed based on the ultrasonic criteria suggested by the Chinese Medical Association.¹² The criteria are described as follows: (1) diffuse enhancement of near-field echo in the hepatic region (stronger than in the kidney and spleen region) and gradual attenuation of the far-field echo, (2) unclear display of intra-hepatic lacuna structure, (3) mild to moderate hepatomegaly with a round and blunt border, and (4) reduction of the blood flow signal in the liver but with a normal distribution of blood flow as shown by color Doppler ultrasonography. NAFLD was diagnosed if item 1 and any one or more items 2–4 were matched. A trained ultrasonographer performed the hepatic ultrasonic examination in a blinded manner. Patients were included if they had available ultrasound and blood test results in the hospital information system and had undergone Transient Elastography (TE) examinations within the study period. Patients with incomplete data were excluded from the analysis.

Other exclusion criteria were evidence of other chronic liver diseases, including hepatitis B or C, autoimmune hepatitis (AIH) (as indicated by testing positive for autoimmune antibodies, demonstrating a favorable response to steroids, those on hepatotoxic medications, such as chronic methotrexate, were also excluded, as well as those with advanced liver disease, cardiac failure, and hepatic congestion. In addition, those with very high body mass index (BMI) who could not undergo TE examinations for other reasons, and those with clinical or ultrasound evidence of decompensated cirrhosis, and patients with daily alcohol intake greater than 20 g history (during the previous 5 years) were also excluded from the study (Figure 1).

Clinical and Laboratory Data

Clinical and laboratory data were obtained from 165 eligible patients. Demographic and baseline data (patient age, sex, BMI), laboratory information on levels of ALT and AST, alkaline phosphatase (ALP), total serum cholesterol, triglycerides, low-density lipoprotein (LDL), high-density lipoprotein (HDL), fasting blood sugar (FBS), partial thromboplastin time (PTT), serum platelet count, and serum gamma-glutamyl transpeptidase (GGT) were recorded. Laboratory indices were measured using standard techniques. To determine ALT healthy range in the study population, after excluding patients with positive viral markers, regular drug users, and alcohol drinkers, serum ALT upper normal limit (the 95th percentile) was set at 40 U/L. This reference laboratory cut-off value of 40

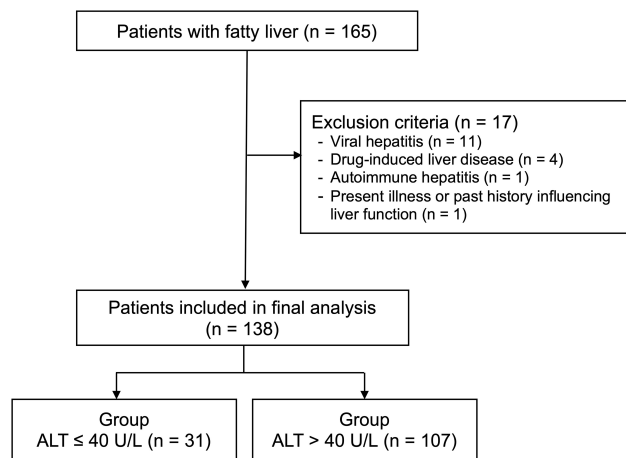

Figure 1 Flow chart of the study.

U/L was used to classify ALT activity as “normal” and “elevated” according. Thus, 27 NAFLD patients had normal ALT levels (≤ 40 U/L), while the remaining 138 patients had elevated ALT levels (> 40 U/L). All the measured baseline, clinical, and laboratory findings were compared between the two groups.

Liver Stiffness Measurements

An Echosens FibroScan (42 Rue Monge 74,005, Paris, France) was used in this study. The manufacturer’s guidelines and findings from previous studies indicate that 10 valid TE readings are necessary for a test to be deemed successful.^{13–15} A success rate greater than 70% was achieved for all patients included in the study. The following fibrosis stages were defined based on several previous studies and the manufacturer’s references: F0 1–6, F1 6.1–7, F2 7–9, F3 9.1–10.3, and F4 ≥ 10.4 .¹⁶ Enrolled NAFLD patients’ fibrosis stages were evaluated and compared between the two groups with normal and elevated ALT levels.

Statistical Analysis

All statistical analyses were conducted using the SPSS software package version 20 for Windows (SPSS, Inc., Chicago, IL). Independent-sample Student’s *t*-test and Mann–Whitney *U*-test were used to test the differences between parametric and non-parametric variables in the two study groups. Categorical variables were analyzed using the Chi-square test. Kendall τ was used to determine the correlation between the TE results and the AST, ALT, and AST/ALT ratios. Receiver operating characteristic (ROC) curve analysis was performed. The area under the

curve (AUC) and the diagnostic values of each cut-off point, including sensitivity and specificity, were calculated to determine a better cut-off value for serum ALT to detect more advanced stages of fibrosis in patients with NAFLD. Statistical significance was set at p -value < 0.05 . A study power of 80% was assumed in the analysis.

Result

Baseline Characteristics

The baseline characteristics of the NAFLD patients are summarized in Table 1. Among the 165 patients enrolled in this study, 138 were diagnosed with NAFLD, including 82 (59.4%) males and 56 (40.6%) females. They had a mean age of 41 ± 11 years (range: 30–52); 71.0% (98/138), were overweight (BMI > 25 kg/m²) at baseline. Diabetes and hypertension were the major comorbidities (20.3% and 15.9%, respectively). The mean \pm SD serum ALT, AST, and GGT levels were 63 ± 32 , 57 ± 34 , and 65 ± 29 U/L, respectively.

Clinical Characteristics Regarding Elevated ALT

The baseline and clinical characteristics of NAFLD patients stratified by serum ALT levels are shown in Table 2. Age and sex of the patients were not significantly different between the two groups ($p = 0.142$ and $p = 0.096$, respectively). The mean \pm SD serum total cholesterol and AST levels were significantly higher in those with elevated

Table 1 Baseline Characteristics of NAFLD Patients

Variable	Total (n = 138)
Age (y) (Mean \pm SD)	41 \pm 11
Gender [No. (%)]	
Male	82 (59.4%)
Female	56 (40.6%)
BMI (kg/m ²) (Mean \pm SD)	25.62 \pm 3.21
Obesity (>25)	98 (71.0%)
Co-morbidities	
Diabetes	28 (20.3%)
Hypertention	22 (15.9%)
Sleep disorders	17 (13.3%)
Gout	8 (5.8%)
ALT (U/L)	63 \pm 32
AST (U/L)	57 \pm 34
GGT (U/L)	65 \pm 29

LDL-Cholesterol (mg/dL) (Mean ± SD)	125 ± 40	124 ± 26	126 ± 40	0.821
Platelet count (/L) (Mean ± SD)	344,519 ± 478,237	501,653 ± 835,478	326,792 ± 425,437	0.751
AST (U/L) (Mean ± SD)	57 ± 34	26 ± 13	61 ± 31	< 0.001
GGT (U/L) (Mean ± SD)	65 ± 29	60 ± 29	69 ± 27	0.385
ALP (U/L) (Mean ± SD)	183 ± 182	132 ± 62	195 ± 192	0.187
LMS (kPa) (Mean ± SD)	12.12 ± 12.60	9.24 ± 4.89	9.03 ± 7.67	0.071

Abbreviations: ALT, alanine aminotransferase; AST, aspartate aminotransferase; GGT, gamma glutamyl transferase; LDL, low-density lipoprotein; LMS, liver stiffness measurement.

ALT (208 ± 49 vs 177 ± 37 mg/dL, $p = 0.013$) and (61 ± 31 vs 26 ± 13 U/L, $p < 0.001$), respectively. There was no significant difference in triglyceride, LDL cholesterol, platelet count, GGT, and ALP between the two groups ($p = 0.472$, 0.821, $p = 0.751$, $p = 0.385$ and $p = 0.187$, respectively).

Relationship Between Serum ALT, AST Levels and Stages of Fibrosis of Patients with NAFLD

All patients diagnosed with fatty liver on ultrasound had successful TE. The mean stiffness score was 12.12 ± 12.60 kPa, and most patients exhibited either no fibrosis or an

advanced level of the disease. The distribution of patients according to the stage of liver fibrosis is shown in Table 3. The proportion of significant liver fibrosis in patients with normal ALT level was 51.6%. The most common liver fibrosis stages were F0, with 47 (34.1%) and F1 with 32 (23.2%). There was no significant difference in AST and GGT levels in terms of liver stiffness. Association between serum ALT levels and liver fibrosis showed that in the non-fibrous NAFLD group (F0), there was no statistically significant difference between the normal (48.4%) and elevated ALT groups (29.9%) ($p = 0.109$). There was no significant difference in the F1 and F2 between the two groups ($p = 0.469$ and $p = 0.371$, respectively). When considering the cases of advanced fibrosis in the analysis, the ALT level was significantly higher

Table 3 Liver Fibrosis Characteristics of NAFLD Patients Stratified by Serum ALT Level

Finding	Total (n = 138)	Groups of Patients		p value
		ALT ≤ 40 U/L (n = 31)	ALT > 40 U/L (n = 107)	
F0 [No. (%)]	47 (34.1%)	15 (48.4%)	32 (29.9%)	0.109
F1 [No. (%)]	32 (23.2%)	8 (25.8%)	24 (22.4%)	0.469
F2 [No. (%)]	26 (18.8%)	6 (19.4%)	20 (18.7%)	0.371
F3 [No. (%)]	18 (13.0%)	1 (3.2%)	17 (15.9%)	0.0013
F4 [No. (%)]	15 (10.9%)	1 (3.2%)	14 (13.1%)	0.0047

in NAFLD patients who had advanced fibrosis (F3, F4) (3.2% vs 15.9%, $p = 0.0013$; 3.2% vs 13.2%, $p = 0.0047$, respectively).

Receiver Operating Characteristics (ROC) Curve Analysis

The ROC curve analysis revealed that the serum concentration of ALT could significantly predict the involvement of advanced fibrosis (F3, F4) in mild fibrosis (AUC = 0.602, $p = 0.021$, Figure 2). In addition, NAFLD patients with mild to moderate fibrosis (F1-F2) were detected at a cut-off value of 59 U/L with 67% sensitivity and 51% specificity, while patients with severe fibrosis and/or cirrhosis (F3-F4) were detected at a cut-off value of 81 U/L with 53% sensitivity of and 67% specificity.

TE fibrosis scores were significantly correlated with the AST/ALT ratio (Figure 3). The AST/ALT ratio was a significant predictor of advanced fibrosis (AUC = 0.829, $p = 0.001$). A cut-off value of the ratio for detecting patients with severe fibrosis and/or cirrhosis was 0.87 with 86.9% sensitivity and 79.8% specificity.

Discussion

The prevalence of NAFLD in Western countries is estimated to be 17% to 46%, depending on the population.¹⁷ NAFLD prevalence among the Vietnamese population

Figure 2 ROC curve of serum ALT level predicts more than 32% hepatocytes involvement in hepatosteatosis of patients with NAFLD without advanced fibrosis. Area under curve [AUC] = 0.602, $p = 0.021$.

Figure 3 ROC curve of AST/ALT ratio predicts advanced fibrosis in NAFLD patients. Area under curve (AUC)= 0.829, $p=0.001$.

increased due to improved socioeconomic status and Western lifestyle adoption, especially in the urban population. NAFLD covers a range of conditions, from simple steatosis to NASH and fibrosis.¹ Fibrosis and inflammation may eventually progress to cirrhosis in up to 20% of patients.¹⁸ A recent large UK study found that NAFLD detected by ultrasound was the most common cause of abnormal liver biochemistry.¹⁹ ALT is found in the cytosol of hepatocytes, where it transfers amino groups, while the major site for AST is the mitochondria.²⁰ ALT is a specific marker of liver inflammation and hepatocellular injury²¹ and is commonly used as a liver disease indicator. Recent observational studies have suggested that liver damage already exists even when ALT levels are within the normal range. Thus, a diagnosis of elevated serum ALT levels might underestimate the prevalence of NAFLD.²²

In this study, we found that the current cut-off value of 40 U/L was not significantly different between patients with NAFLD and non-fibrous findings. Normal liver enzyme levels have been demonstrated in subjects with the entire spectrum of NAFLD; therefore, some studies based on liver enzyme screening reported a lower prevalence of NAFLD (3–12%) than imaging or histology-based studies consistently.²³ NAFLD is usually caused by abnormal metabolism in patients and is closely associated with dyslipidemia, diabetes mellitus, and obesity.¹⁶

Previous large population-based studies showed that abnormal ALT levels (ALT > 43 U/L) are present in 2.8% of the adult population, which increases to 6.6% in class II or III obesity.²⁴ Using the same ALT cut-off value (43 U/L), Kunde et al showed elevated ALT levels in 8.6% of their study population, which consisted of women with class II or III obesity.²⁵ However, we used a cut-off value of 40 U/L for ALT in this study; according to this level, 92 (86%) of 107 patients had abnormal ALT levels. There was no statistically significant difference in non-fibrous findings (F0) to mild fibrosis (F1-F2) in our results.

Previous studies have demonstrated that the occurrence of significant fibrosis in NASH might be seen in patients with NAFLD who have a normal ALT value.^{10,13} Fracanzani et al reported that normal ALT levels correlated with less severe steatosis and necroinflammation. However, no correlation was observed between the severity of fibrosis and ALT levels. They considered ALT values \leq 40 U/L to be normal.²² Fracanzani AL et al study was also in concordance with these findings, as results showed correlation between abnormal ALT levels and severity of fibrosis in these patients.²² Our results showed that the ALT level of 59 U/L is required to detect mild to moderate fibrosis (F1-F2) in NAFLD patients, and 81 U/L is required to detect severe fibrosis (F3-F4). The AST/ALT ratio was 0.87, which was used to predict progressive fibrosis with severe fibrosis and/or cirrhosis. This ratio is lower than that reported by Angulo et al, who suggested AST/ALT ratio <1 in patients with no mild fibrosis or fibrosis. The ratio > 1 reflects the severe progression of NAFLD.

There are some limitations to this study. The study is observational; thus, a causal relationship cannot be established. Secondly, NAFLD was diagnosed by ultrasonography, not by liver biopsy, which is the gold standard, though invasive. Future larger multi-center cohort studies with liver biopsy should be considered while measuring ALT level to identify the correlation with liver stiffness stages more precisely.

Conclusion

In conclusion, it appears that using ALT level as a marker for severe NAFLD would result in considering high-risk patients as mild cases as with normal ALT, even though there is still the risk of progressive and severe hepatic disease. Our study underlines the small contribution of ALT as an independent factor for detecting the severity of NAFLD. Therefore, using ALT levels as an indicator of

severity might result in false reassurance for patients and physicians.
