

Since January 2020 Elsevier has created a COVID-19 resource centre with free information in English and Mandarin on the novel coronavirus COVID-19. The COVID-19 resource centre is hosted on Elsevier Connect, the company's public news and information website.

Elsevier hereby grants permission to make all its COVID-19-related research that is available on the COVID-19 resource centre - including this research content - immediately available in PubMed Central and other publicly funded repositories, such as the WHO COVID database with rights for unrestricted research re-use and analyses in any form or by any means with acknowledgement of the original source. These permissions are granted for free by Elsevier for as long as the COVID-19 resource centre remains active.

Keywords:

COVID-19 in India
Age and sex-specific death rate
Comorbidities of COVID-19
Time interval between infection and death

ABSTRACT

Background: As the number of COVID-19 cases continues to rise, public health efforts must focus on preventing avoidable fatalities. Understanding the demographic and clinical characteristics of deceased COVID-19 patients; and estimation of time-interval between symptom onset, hospital admission and death could inform public health interventions focusing on preventing mortality due to COVID-19.

Methods: We obtained COVID-19 death summaries from the official dashboard of the Government of Tamil Nadu, between 10th May and July 10, 2020. Of the 1783 deaths, we included 1761 cases for analysis.

Results: The mean age of the deceased was 62.5 years (SD: 13.7). The crude death rate was 2.44 per 100,000 population; the age-specific death rate was 22.72 among above 75 years and 0.02 among less than 14 years, and it was higher among men (3.5 vs 1.4 per 100,000 population). Around 85% reported having any one or more comorbidities; Diabetes (62%), hypertension (49.2%) and CAD (17.5%) were the commonly reported comorbidities. The median time interval between symptom onset and hospital admission was 4 days (IQR: 2, 7); admission and death was 4 days (IQR: 2, 7) with a significant difference between the type of admitting hospital. One-fourth of (24.2%) deaths occurred within a day of hospital admission.

Conclusion: Elderly, male, people living in densely populated areas and people with underlying comorbidities die disproportionately due to COVID-19. While shorter time-interval between symptom onset and admission is essential, the relatively short time interval between admission and death is a concern and the possible reasons must be evaluated and addressed to reduce avoidable mortality.

1. Background

As of July 10, 2020, the SARS-CoV-2 has infected around 820,000 individuals with 22,000 deaths in India.¹ Tamil Nadu, a south Indian state with a population of around 72 million,² reported around 130,000 cases and 1829 deaths which was 16% of total confirmed cases and 8.3% of total deaths in India.³ The rapid spread of the disease has undoubtedly become a burden to health systems in several countries, as a significant proportion of elderly, immunosuppressed and those with underlying metabolic, cardiovascular or respiratory diseases continue to develop

severe forms of COVID-19 and are at an increased risk for adverse outcomes.⁴ At the same time, evidence is emerging to caution that young and adult general population are also at considerable risk for critical illness and adverse outcome.⁵

As the number of cases continues to increase, public health efforts must focus on preventing avoidable fatalities. When a health system is burdened beyond its capacity and the morale of health care workers is affected, the standard of care would be compromised, leading to negative health outcomes. Current therapeutic strategies to deal with COVID-19 are only supportive, and prevention efforts aimed at reducing

transmission in the community are considered as the most effective methods.⁶ However, fatality due to COVID-19 could be reduced, if there is early and accurate diagnosis, identification of clinical features of severe risks, prediction of disease progression and appropriate clinical intervention. Further, early seeking of medical care by people with exposure and symptoms, especially the most vulnerable, could substantially reduce the spread of infection, severity and fatality due to this disease and produce better clinical outcome.⁷

Currently, COVID-19 has its presence across the globe, generating new information, fresh knowledge and evidence continuously. However, there are still many unknowns and ambiguity about the demographic and clinical characteristics of deceased COVID-19 patients; the different time intervals between the time of infection and outcome - death or recovery.⁸ The currently available literature indicates varying information across regions and countries, emphasizing the need for generating evidence for a specific geography, population, and context.

This study aims to understand the demographic and clinical characteristics of deceased COVID-19 patients; and estimate the time-interval between symptom onset, hospital admission and death, which could inform public health interventions focusing on preventing mortality due to COVID-19.

2. Methods

We obtained COVID-19 death summaries from the official dashboard of the Government of Tamil Nadu (<https://stopcorona.tn.gov.in/>), a South Indian state. Each death summary consisted of information such as district, age, gender, type of admitting hospital, presence of comorbidities, presenting symptoms, number of days with symptoms, date of hospital admission and date of death. We collected information from May 10, 2020 to July 10, 2020.

A total of 1783 deaths were reported during the period. We excluded 22 brought dead cases and finalised 1761 cases of deaths for analysis. For the analysis of comorbidities, we included only the cases that reported the presence or absence with details of comorbidities. For the analysis of presenting symptoms, we included only the death summaries that indicated the presence of symptoms with details, as the absence of symptoms on admission is not provided in death summaries. For the estimation of time intervals between symptom onset and hospital admission; admission and death, we excluded the cases referred from other hospitals due to the potential influence on the time intervals; and cases who did not have all the information.

We summarised the categorical variables as frequency and percentages; and continuous variables as mean, standard deviation (SD), median, and interquartile range (IQR) as appropriate. We analysed the continuous variables using independent t-test or Mann-Whitney test/Kruskal-Wallis H test. The proportions for categorical variables were analysed using Chi-squared test (χ^2) test. The analyses were performed using SPSS version 24.0 (IBM Corp. Armonk, NY, USA).

3. Results

3.1. Socio-demographic characteristics and age, sex-specific mortality

Table 1 summarizes the details of deaths that were reported during the period of analysis. The mean age of the deceased was 62.5 years (SD: 13.7 years) without a significant difference between male (62.8 years; SD: 13.6) and female (61.8 years; SD: 14.2). The majority of the deceased were male (71.4%). Chennai district, which is the state capital reported around 67% of all deaths reported in the state. Around 71% (1246) of deaths were recorded in public hospitals and the remaining 29% (515) occurred in private hospitals.

The crude death rate was 2.44 per 100,000 population (95% CI: 2.43, 2.45); the age-specific death rate was found to be highest (22.72 per 100,000; 95% CI: 22.48, 22.97) among population aged above 75 years and lowest among children aged less than 14 years (0.02 deaths per

Table 1

Age, gender, hospital and geographic specific death rate (n=1761).

	Description	No of deaths (%)	Death per 100,000 people	95% Conf. Interval	P Value
Age	Up to 14	4 (0.2)	0.02	0.02, 0.03	<0.001
	14 to 29	26 (1.5)	0.13	0.13, 0.14	
	30 to 44	161 (9.1)	0.96	0.95, 0.98	
	45 to 59	457 (26.0)	3.97	3.93, 4.00	
	60 to 74	783 (44.5)	12.93	12.84, 13.02	
	75 and above	330 (18.7)	22.72	22.48, 22.97	
Gender	Male	1258 (71.4)	3.48	3.46, 3.50	<0.001
	Female	503 (28.6)	1.40	1.38, 1.41	
Admitting Hospital	Public	1246 (70.8)	–	–	
	Private	515 (29.2)	–	–	
Geography	Chennai (Capital)	1182 (67.1)	25.44	25.29, 25.58	<0.001
	Other districts	579 (32.9)	0.86	0.85, 0.86	
	Total	1761 (100)	2.44	2.43, 2.45	

100,000 children; 95% CI: 0.02, 0.03). The age-specific death rate increased as the age increased. The death rate was significantly higher among men (3.5 per 100,000 population; 95% CI: 3.46, 3.50) compared to women (1.4 per 100,000 population; 95% CI: 1.38, 1.41). Chennai district recorded a significantly higher death rate of 25.44 per 100,000 (95% CI: 25.29, 25.58), while all the other districts together recorded 0.86 deaths per 100,000 population (95% CI: 0.85, 0.86).

3.2. Pre-existing comorbidities in deceased COVID-19 patients

Among the 1,678 cases that reported the presence or absence with details of comorbidities, 85.3% reported any one or more comorbidities at the time of hospital admission (**Table-2**). Diabetes was found to be the most common comorbidity associated with 62% of the deceased; hypertension and CAD were present among 49.2% and 17.5% of the deceased respectively. The coexistence of diabetes and hypertension; and coexistence of diabetes, hypertension and CAD were found in 36.6% and 8.7% of the individuals respectively.

As expected, the study found a significantly higher presence of comorbidities among the elderly compared to younger age groups ($p < 0.001$) in terms of the presence of any one or more comorbidities, diabetes, hypertension, chronic obstructive pulmonary disease (COPD), coronary artery disease (CAD), coexistence of diabetes and hypertension, and coexistence of diabetes, hypertension and CAD. As age increased, the presence of comorbidities seems to increase significantly. The presence of any one or more comorbidities ($p = 0.002$) and comorbidities categorised as others ($p < 0.001$) were found to be higher among women. Private hospitals reported to have treated a significantly higher proportion of deceased patients with comorbidities such as diabetes ($p = 0.01$), hypertension ($p < 0.001$), CAD ($p < 0.06$), asthma ($p < 0.06$), the coexistence of diabetes and hypertension ($p < 0.001$), and the coexistence of diabetes, hypertension and CAD ($p = 0.007$), whereas public hospitals reported to have treated higher proportion of patients with CKD ($p < 0.001$). Around 18% of deceased reported having other comorbidities such as hypothyroidism, dementia, encephalopathy, cerebrovascular diseases (CVS), hepatitis etc., however, the presence of these as independent comorbidity was found to be very low (3.6%, 61).

Table 2
Age, gender and hospital specific comorbidities.

Presence of comorbidities	Gender			Age Groups (in years)					Admitting hospital			Total (n - 1678)
	Male (n - 1194) % (n)	Female (n - 484) % (n)	P Value	< 45 (n - 189) % (n)	45 to 59 (n - 454) % (n)	60 to 74 (n - 735) % (n)	>75 (n - 300) % (n)	P Value	Private(n - 493)	Public(n - 1185)	P Value

Abbreviations: Chronic obstructive pulmonary disease (COPD); Chronic Kidney Disease (CKD); Coronary artery disease (CAD); Diabetes Mellitus (DM); Hypertension (HTN)

3.3. Presenting symptoms on hospital admission

Around 583 deaths summaries consisted of the details of presenting symptoms on admission (Table-3). Fever was the most common presenting symptom (78.7%) reported by 80.5% of the deceased men and 73.7% of women. Breathing difficulty was reported by 75.8% of the patients (76.1% of men, 75% of women); around 53% had cough (54.8% of men and 49.3% of women) and 35.8% had fever, cough and breathing difficulty together (37.4% of men and 31.6% of the women), however, the differences are not statistically significant. Diarrhoea and generalised weakness/myalgia were reported by 6.2%, and 7.5% of the patients respectively, with women reporting significantly higher than men (p = 0.01; p = 0.02). Fever was reported to be significantly higher among the older population (p = 0.001).

3.4. Time intervals between symptom onset and hospital admission; admission and death

The median time interval between onset of symptoms and hospital admission was 4 days (IQR: 2, 7) without significant difference among gender and age groups (Table-4). The patients who were admitted in private hospitals had a median of 4 days of symptoms as compared to public hospital patients with 3 days of symptoms on admission (P < 0.005).

The median time interval between hospital admission and death was 4 days (IQR: 2, 7) and there are no significant differences among gender and age groups. However, it was significantly higher, 6 days (IQR: 2, 10) in private hospitals compared to 3 days (IQR: 1, 6) in public hospitals (p < 0.001). Around one fourth (24.2%) of the reported deaths occurred within a day of hospital admission (public 27.8%; private 15.3%), 23.7% between 2 and 3 days (public 26.6%; private 16.7%), 8.1% between 4 and 5 days (public 8.5%; private 7.2%) and 43.4% occurred after 5 days of admission (public 36.5%; private 60.2%) (p < 0.001).

Table 3
Age, gender and hospital specific presenting symptoms

Presenting symptoms	Gender			Age Groups in years				P value	Admitting hospital			Total (n - 583)
	Male (n - 431) % (n)	Female (n - 152) % (n)	P value	< 45 (n - 34) % (n)	45 to 59 (n - 153) % (n)	60 to 74 (n - 257) % (n)	>75 (n - 139) % (n)		Private(n - 495)	Public (n - 88)	P Value

4. Discussion

It is well documented that the COVID-19 pandemic takes different shapes and forms with varying mortality levels across geographic regions and countries. Though there are several studies from other countries that explained the characteristics of COVID-19 deaths, there is a dearth of peer-reviewed and published literature from India. Our study analysed the individual death summaries, and described the demographic and clinical characteristics of deceased COVID-19 patients; and estimated the time intervals between symptoms onset to hospital admission and death, which are critical for developing context and geographic-specific public health interventions focusing on reducing the mortality.

Our study findings indicated a disproportionate death rate among the categories of age, gender and geography. It is well demonstrated that age is the most significant risk factor for death due to COVID-19 and our study confirms the existing evidence. The increasing death rate with age is expected and it could be due to the higher prevalence of comorbidities, the reduced and less responsive innate and adaptive immune system among the elderly.^{9,10} The study reported a higher proportion of deaths (71%) among men, though the proportion of total confirmed male cases was only 61% in the state¹¹; and death per 100,000 male population was 3.4 as compared to 1.4 deaths per 100,000 female population. The less mortality among women has been reported in many studies which could be due to the protection of X chromosome and sex hormones, which play an important role in providing innate and adaptive immunity.¹² The higher mortality among men could be due to the behavioral risk factors such as smoking, and alcohol consumption, which are relatively higher among men in India.¹³ Around 67% of deaths occurred in the capital district/city that recorded 58% of the total cases and just 6.4% of the population of the state. It is also the smallest and densest of all the districts in the state.² The possible reasons could be lack of timely access to healthcare facilities, delayed seeking of care, overwhelming of health system with sudden surge of cases due to larger and exponential spread of the virus in the city.

The disease severity, increased admission rate in the intensive care units (ICU), and increased risk of mortality of COVID-19 are strongly associated with comorbidities such as diabetes, hypertension, obesity, cardiovascular disease, and respiratory system diseases and our study results confirm the previous findings.^{4,14,15} A study showed a hazard ratio of 2.59 among patients with two or more comorbidities compared to 1.79 among patients with one comorbidity.⁴ The Centers for Disease Control and Prevention reported 12 times higher deaths among patients with reported underlying conditions compared with those without reported underlying conditions (19.5% versus 1.6%).¹⁶ In our study, the prevalence of any one or more comorbidities among the deceased was found to be around 85%, and a significant proportion of deceased having other comorbidities such as diabetes, hypertension, and CAD respectively, with a strong association with age. Studies in China reported around 70% of deaths with any one comorbidity^{4,17}, South Korea and Brazil reported 83% and 90.7%; and these studies have reported

hypertension, CAD, and diabetes as the main comorbidities among deaths.^{18,19}

In our study, fever and breathing difficulty were each reported among 3/4th of the deceased, cough among half of them and around 1/3rd had fever, breathing difficulty and cough together, which are in line with the existing literature that fever, dry cough, shortness of breath and fatigue were the common symptoms on admission among the deceased patients.^{14,17} A meta-analysis of COVID-19 patients, showed fever (88.8%) as the most common symptom, followed by dry cough (68%) and fatigue.²⁰ Another study that reviewed 24,410 cases across the world showed 78% of the cases with fever and 58% with cough.²¹ Though the study found an association between fever as a presenting symptom and age of the deceased, other symptoms and multiple concurrent symptoms did not indicate any association with age, gender and admitting hospital.

The median time interval between symptom onset and hospital admission was found to be 4 days, which is within the range mentioned in studies from China (4, 10 days), Singapore (4 days), Italy (7 days) that indicated a range of 3–10 days.^{14,22–24} The duration might change during the different phases of the epidemic due to rapid changes in the level of knowledge and awareness, stigma and discrimination, fear of the disease, programmatic interventions, health-seeking behavior, and access to health care services. As the epidemic progresses and there is continuous scale-up of public health and social interventions, the duration is expected to decrease, which could potentially limit the infection to others. According to our study, the median time interval between hospital admission and death was 4 days with a significant difference between patients admitted in private and public hospitals. Other countries reported a slightly higher, but a wide range of 5–16 days of time interval between hospital admission and death.^{14,25–27} A study that reviewed the length of stay across the world reported a shorter length of stay for those who died in hospital compared to those were discharged alive, with medians between 4 and 21 days compared to 4 and 53 days, respectively.²⁸ The shorter period of hospital stay with negative outcome could be due to the delayed seeking of care due to economic reasons and lack of awareness about the disease, shortage of ICU facilities and ventilators, and overwhelming of hospitals that affect the capacity to deliver services effectively. The knowledge and awareness level of health workers, especially about the rapid progression to severe illness, treatment protocols, and the availability of effective drugs could also alter the duration of hospital stay. The relatively longer time interval between hospital admission and death in private hospitals, despite the higher proportion of deceased patients with comorbidities and presence of multiple concurrent symptoms could be due to the availability advanced technology and facilities to provide advanced life-supporting critical care, the affordability of those seeking health care and less burden of patients especially for COVID-19 management as compared to public hospitals.

Studies reported an average incubation period of 4–7 days, which is the time interval between the exposure/infection and onset of symptoms.^{4,22,29} Considering an average of 5 days between the

exposure/infection and onset of symptoms, the estimated time interval between exposure/infection and death is 13 days in the state, whereas the time interval between symptom onset and death is just 8 days. Two studies have reported a higher average time interval of 17.8 and 18.5 days between the first recorded symptoms and death^{10,30}, as compared to our study findings.

5. Conclusion

The study provides evidence from India, emphasizing that the elderly, male and people living in densely populated areas, and patients with underlying comorbidities die disproportionately due to COVID-19. The study estimated a time interval of 13 days between exposure to infection and death, with 4 days each for symptoms onset to hospital admission; and admission to death. None of the potential factors significantly alter the time interval between the onset of symptoms and hospital admission and death, except the type of treating hospital. The shorter time interval between the onset of symptoms and hospital admission would be critical as early diagnosis, supportive care and treatment could substantially reduce the mortality especially among the elderly and vulnerable population. However, the shorter time interval between admission and death is a concern and the possible reasons must be elucidated and addressed. Essentially, as the number of deaths from COVID-19 continues to increase, early diagnosis and timely treatment for moderate and severe cases are of crucial importance to reduce mortality.

6. Limitations

The analysis is based on data available in the public domain and it is limited to only deaths that were reported in the state through hospital admission. Hospital care can vary from general ward care to intensive care and we do not have disaggregated data for this. The data have limitations in terms of completeness such as, the presence of symptoms that were not reported in all the deaths.
