## Abstract

**Background** Lymphangioleiomyomatosis (LAM) is a rare disease that can occur sporadically (S-LAM) or associated with the tuberous sclerosis complex (TSC-LAM). The natural history of LAM is not completely understood, including whether there is a difference between the clinical courses of the two forms. This study aimed to compare the clinical, functional and tomographic features between S-LAM and TSC-LAM, and evaluate the annual rates of change in lung function.

**Methods** This retrospective cohort study included patients with LAM followed up between 1994 and 2019. Clinical, functional and imaging variables were evaluated, and the lung cysts were automatically quantified. Quality of life and predictors of lung function impairment were accessed, and the annual rate of lung function decline was compared between S-LAM and TSC-LAM.

**Results** Of the 107 patients included, 77 had S-LAM and 30 had TSC-LAM. Although patients with TSC-LAM had a higher prevalence of renal angiomyolipomas and neurological and dermatological manifestations, pulmonary function tests were similar. Patients with S-LAM had a greater rate of forced expiratory volume in 1 s decline and a higher extent of cysts. Pneumothorax, desaturation in the 6-minute walking test and a higher extent of lung cysts were predictors of functional impairment. A greater impact on vitality and emotional health was observed in the TSC-LAM.

**Conclusion** Greater functional decline and a higher cystic extension were found in patients with S-LAM. Our study provides a broad clinical, functional and tomographic characterisation of patients with LAM, adding valuable information to the existing evidence to better understand the two forms of the disease.

## Introduction

Lymphangioleiomyomatosis (LAM) is a rare neoplastic disease that predominantly affects women of reproductive age and is caused by mutations in the tuberous sclerosis complex (TSC) genes *TSC1* and *TSC2*, culminating in the hyperactivation of the mechanistic target of rapamycin (mTOR) signalling pathway [1]. LAM causes inappropriate cell growth, proliferation, invasion and metastatic spread of abnormal smooth muscle-like cells (LAM cells), resulting in cystic destruction of the lung parenchyma, and tumour lesions such as lymphangioleiomyomas and renal angiomyolipomas [2–5].

LAM may occur sporadically (S-LAM) or associated with TSC (TSC-LAM), a genetic autosomal dominant disorder characterised by hamartomas in different organs [6–8]. Recent findings have shown that lung cysts suggestive of LAM can complicate TSC in up to 80% of subjects aged >40 years [9–12].

Dyspnoea and spontaneous pneumothorax are the most common clinical manifestations [13, 14]. The clinical course of LAM is heterogenous and may vary from asymptomatic to progressive disease culminating in death or lung transplantation. Previous studies reported that the estimated annual rate of decline in forced expiratory volume in 1 s ( $FEV_1$ ) is 47–134 mL·year<sup>-1</sup> [15].

TSC-LAM is usually considered milder and less progressive than S-LAM. Patients with TSC-LAM often show higher  $FEV_1$  and diffusing capacity of the lung for carbon monoxide ( $D_{LCO}$ ), and a higher proportion of asymptomatic disease [16, 17]. Nonetheless, recent cohorts found no difference between the rate of lung function decline between these two groups, including one involving only patients with incidental diagnosis and asymptomatic disease aiming to eliminate possible selection bias in TSC-LAM group due to preconised screening [15, 16, 18].

The natural history of LAM is mainly derived from retrospective cohort studies and has not yet been completely elucidated, especially the differences between the clinical courses of TSC-LAM and S-LAM [19]. Therefore, we decided to further analyse our cohort of patients with LAM to better understand and compare both groups, with a special emphasis on functional decline. The purpose of this study was to compare the main clinical, functional and radiological features of S-LAM and TSC-LAM, and to investigate the annual rate of change in lung function in our cohort.

## Methods

### *Design and population*

This retrospective cohort study included patients with LAM who were followed up at a tertiary centre from 1994 to 2019. The included patients were at least 13 years old and had a definitive LAM diagnosis according to international guidelines [20]. TSC was diagnosed based on previous recommendations [21]. All variables were accessed at inclusion, which occurred in 2019. The study protocol was approved by the local research ethics committee (79217317.5.0000.0068), and signed informed consent was obtained from all patients.

### *Clinical and demographic data*

Data on the age, number of patients with TSC, time from diagnosis, symptoms, and pulmonary and extrapulmonary manifestations at inclusion and during the course of the disease and treatment were collected. All patients were referred for a dermatological evaluation to investigate the presence of cutaneous manifestations associated with TSC. Quality of life was accessed using the Short Form 36 Health Survey (SF-36) questionnaire, which has been validated in the Brazilian population [22, 23].

### *Pulmonary function tests*

Spirometry was performed using a calibrated pneumotachograph, and lung volumes and  $D_{LCO}$  values were obtained using a body plethysmograph. The following variables were obtained: forced vital capacity (FVC),  $FEV_1$ ,  $FEV_1/FVC$  ratio, total lung capacity (TLC), residual volume (RV), RV/TLC ratio and  $D_{LCO}$ . Predicted values were derived from Global Lung Function Initiative [24–26].

The prevalence of obstructive, restrictive, mixed and nonspecific patterns; positive response to bronchodilators (BD); air trapping; pulmonary hyperinflation; and reduced  $D_{LCO}$  were determined as recommended [25]. Pulmonary function tests (PFTs) performed within 6 months before the clinical evaluation were considered.

Patients with two or more PFTs available during follow-up were included in the analysis to determine the annual rate of change in  $FEV_1$ . The results of all available spirometry tests performed since diagnosis of each patient were collected.

Predictors of lung function impairment defined by  $FEV_1$  below the lower limit of normal (LLN) were identified.

### *6-minute walk test*

The 6-minute walk test (6MWT) was performed according to recommended standards [27, 28]. Peripheral oxygen saturation ( $S_{pO_2}$ ), heart rate, the 6-minute walking distance (6MWD) and breathlessness were recorded.  $S_{pO_2}$  was measured using pulse oximetry (Onyx, model 9500; Nonin, Plymouth, MN, USA) at

rest and at the end of exercise. Breathlessness was evaluated using the modified Borg scale before and after exercise [29]. The 6MWD was expressed as a percentage of reference values for the Brazilian population [30].

### *Imaging tests*

The patients underwent chest computed tomography (CT) in the supine position without intravenous contrast injection. Quantification of the volume of cysts was obtained automatically by densitovolumetry using a computer program (Advantage Workstation Thoracic VCAR software; GE Medical Systems, Milwaukee, WI, USA) and by selecting pixels between  $-1000$  and  $-950$  HU on soft tissue filter images. The total lung volume, volume occupied by cysts, and ratio of abnormal cyst volume to total lung volume were calculated automatically. Image analysis and manual correction were performed by a thoracic radiologist (M. Wanderley). All CT scans were performed in a stable clinical setting within 1 year before clinical evaluation.

Two chest radiologists (M. Wanderley and R.C. Chate) with 8 and 20 years of experience, respectively, performed a qualitative analysis of CT scans to determine the prevalence of other thoracic findings. A consensus was established in cases of divergent opinions.

Other imaging tests performed at inclusion or within a year prior, including cranial CT or magnetic resonance imaging, abdominal CT and transthoracic echocardiography, were reviewed to assess the presence of TSC neurological manifestations, angiomyolipomas, lymphangiomyomas and cardiac rhabdomyomas.

### *Statistical analysis*

Data are reported as  $n$  (%), as  $\text{mean} \pm \text{SD}$  for variables with a normal distribution and as median (25th–75th percentiles) for variables with a non-normal distribution. The Shapiro–Wilk test was used for normality. Continuous variables were compared using the unpaired  $t$ -test or Mann–Whitney  $U$ -test, whereas categorical variables were compared using Fisher's exact or chi-square tests.

Univariate logistic regression analysis was performed to select the variables associated with  $\text{FEV}_1$  below LLN. Variables that resulted in  $p \leq 0.1$  were included in multivariate analysis using the stepwise forward likelihood ratio logistic regression model to predict factors that were related to lung function impairment. The level of statistical significance was set as  $p \leq 0.05$  for variables to be included in the final model. Odds ratios (OR) and 95% confidence intervals were determined.

The annual rate of change (slope) of  $\text{FEV}_1$  was calculated using linear regression. An adjusted analysis was performed using mixed-effects models with a random intercept and random slope to estimate the decline in  $\text{FEV}_1$  over time. These data were compared between TSC-LAM and S-LAM groups and are reported as  $\text{mean} \pm \text{SE}$ .

All statistical analyses were performed using SPSS software (version 21.0; IBM Inc., Chicago, IL, USA), and statistical significance was set at  $p \leq 0.05$ .

## **Results**

### *Clinical and demographic features, and treatment description*

Among the 116 patients regularly followed up at our centre, two refused to participate in the study and seven were excluded due to a previous pulmonary transplant. Finally, our study included 107 women with a definitive diagnosis of LAM and a mean age of  $43 \pm 11$  years. Of the 107 patients, 72% had S-LAM and 28% had TSC-LAM. Patients with TSC-LAM were younger at the time of inclusion and diagnosis. Diagnosis was confirmed in all patients with TSC-LAM using a combination of clinical and tomographic findings. However, lung biopsy was necessary to confirm the diagnosis in 42% of the patients with S-LAM. The most frequent clinical manifestations were dyspnoea (57%) and spontaneous pneumothorax (50%), with no intergroup differences. Table 1 summarises the patients' clinical and demographic characteristics.

At the time of inclusion, 35% of all LAM patients were taking mTOR inhibitors, with no significant difference between the two groups. Renal angiomyolipoma (23%) and lung function decline (18%) were the main reasons for the use of mTOR inhibitors in patients with TSC-LAM and S-LAM, respectively. Continuous oxygen supplementation was prescribed to 9% of the patients (table 1).

Values are expressed as mean±SD, median (25th–75th percentile) or n (%). LAM: lymphangioliomyomatosis; TSC: tuberous sclerosis complex; BMI: body mass index; mMRC: modified Medical Research Council; mTOR: mechanistic target of rapamycin; S-LAM: sporadic LAM. #: n expressed in each column, respectively: 106 (total), 76 (S-LAM) and 30 (TSC-LAM); ¶: n expressed in each column, respectively: 106 (total), 77 (S-LAM) and 29 (TSC-LAM); †: all patients using sirolimus; §: n expressed in each column, respectively: 105 (total), 75 (S-LAM) and 30 (TSC-LAM).

### Extrathoracic manifestations

Extrathoracic manifestations are presented in table 2. More than half of the patients had renal angiomyolipomas, which were significantly more prevalent in patients with TSC-LAM. There was no difference in the prevalence of lymphangioliomyomas between the two groups. Imaging findings suggestive of neurological impairment were observed in 73% of the patients with TSC-LAM. The most frequent cutaneous manifestation was facial angiofibroma (28%), with a higher prevalence in the TSC-LAM group.

### Pulmonary function tests

The functional data are presented in table 3. ~50% of all LAM patients had normal PFTs. The most frequent abnormalities observed were reduced  $D_{LCO}$  (46%), air trapping (41%) and obstructive impairment (40%), with no significant intergroup differences. Functional variables were similar between the two

Values are expressed as n (%). LAM: lymphangiomyomatosis; TSC: tuberous sclerosis complex; S-LAM: sporadic LAM. <sup>#</sup>: n expressed in each column, respectively: 103 (total), 73 (S-LAM) and 30 (TSC-LAM). <sup>¶</sup>: n expressed in each column, respectively: 95 (total), 68 (S-LAM) and 27 (TSC-LAM). <sup>+</sup>: n expressed in each column, respectively: 105 (total), 75 (S-LAM) and 30 (TSC-LAM).

groups, except for FEV<sub>1</sub>/FVC and TLC, which were lower in the S-LAM and TSC-LAM groups, respectively.

Previous pneumothorax, mMRC dyspnoea score, the distance walked and desaturation  $\geq 4\%$  in the 6MWT, the extent of pulmonary cysts and lymphatic involvement were identified as predictors of FEV<sub>1</sub> below LLN in the univariate logistic regression. Previous pneumothorax (OR 3.206,  $p=0.050$ ), desaturation  $\geq 4\%$  in the 6MWT (OR 7.026,  $p=0.004$ ) and higher extent of lung cysts (OR 1.150,  $p=0.005$ ) persisted as independent factors for FEV<sub>1</sub> below LLN in the multivariable logistic regression (supplementary table S1).

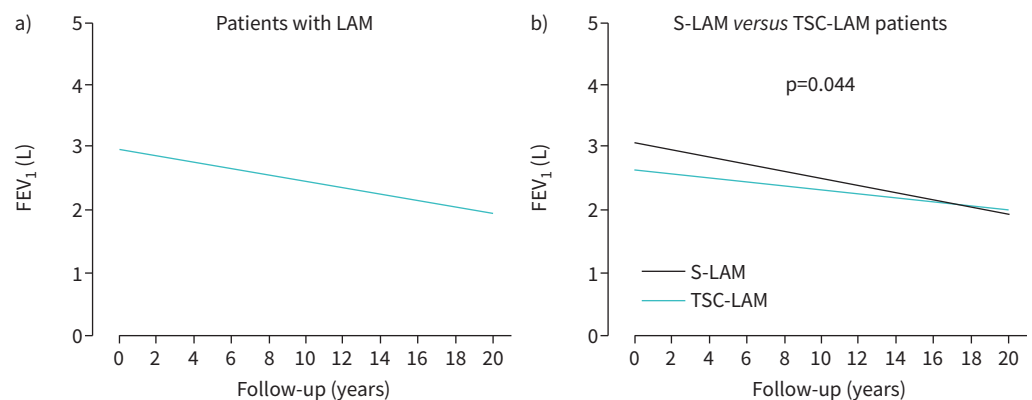

82 patients (63 with S-LAM and 19 with TSC-LAM) were included in the analysis of the annual rate of change in FEV<sub>1</sub>. The median follow-up interval (years) and the number of PFTs were 6 (3–6) and 5 (3–8) in S-LAM patients, and 4 (2–7) and 4 (2–6) in those with underlying TSC, with no significant differences observed between groups ( $p=0.079$  and  $p=0.089$ , respectively). The mean $\pm$ SE FEV<sub>1</sub> decline for all LAM patients was 51.7 $\pm$ 4.7 mL $\cdot$ year<sup>-1</sup>, and patients with S-LAM presented a significantly higher annual decline compared to those with TSC-LAM (55.8 $\pm$ 5.08 mL *versus* 31.7 $\pm$ 10.6 mL,  $p=0.044$ ) (figure 1). An adjusted analysis was conducted, incorporating initial FEV<sub>1</sub>, the use of mTOR inhibitor and age as covariates in the model. The patients with S-LAM persisted with higher rate of FEV<sub>1</sub> decline.

The same analysis performed on patients not treated with mTOR inhibitors (47 S-LAM and seven TSC-LAM) yielded a higher annual rate of FEV<sub>1</sub> decline in S-LAM (51.3 $\pm$ 5 mL *versus* 7.4 $\pm$ 12.3 mL,  $p=0.002$ ) (supplementary figure S1). Additionally, we compared the slopes between the S-LAM and TSC-LAM groups, including patients who died or underwent lung transplantation. There was a tendency to higher annual rate of FEV<sub>1</sub> decline in S-LAM (59.5 $\pm$ 5.3 mL *versus* 35.7 $\pm$ 11.6 mL,  $p=0.067$ ) (supplementary figure S1).

Values are expressed as mean±SD or median (25th–75th percentile). 6MWT: 6-minute walk test; SF-36: Short Form 36 Health Survey; LAM: lymphangiomyomatosis; TSC: tuberous sclerosis complex; S<sub>pO<sub>2</sub></sub>: peripheral oxygen saturation; HR: heart rate; S-LAM: sporadic LAM. <sup>#</sup>: four patients from the initial sample did not perform the SF-36 questionnaire due to the following reasons: cognitive impairment (two) and refusal to answer (two). <sup>†</sup>: n expressed in each column, respectively: 99 (total), 72 (S-LAM) and 27 (TSC-LAM); eight patients from the initial sample could not perform the 6MWT due to the following reasons: osteoarticular limitation (two), cognitive impairment (three), pregnancy (one), loss of follow-up (one) and refusal to perform the test (one). <sup>‡</sup>: n expressed in each column, respectively: 98 (total), 71 (S-LAM) and 27 (TSC-LAM). <sup>§</sup>: n expressed in each column, respectively: 97 (total), 70 (S-LAM) and 27 (TSC-LAM).

#### 6MWT and SF-36 questionnaire

6MWT and SF-36 datasets are shown in table 4. The median distance walked was 495 m (435–559 m), which corresponded to 86% (72–96%) of the predicted distance, with no difference observed between the two groups. The S-LAM group showed lower S<sub>pO<sub>2</sub></sub> at the end of the 6MWT (93% (88–95%) versus 96% (88–97%), p=0.044).

The SF-36 questionnaire showed the lowest scores for role limitations owing to emotional health and vitality in patients with TSC-LAM.

#### Chest high-resolution computed tomography

Chest CT was available for automatic cystic quantification in 86% of the patients. Patients with S-LAM presented with a greater extent of lung cysts than those with TSC-LAM (5.1% (1.2–13.6%) versus 1.2% (0.2–7.8%), p=0.027). CT scans with different extents of cysts are shown in figure 2.

The most prevalent thoracic findings were sclerotic bone lesions (22%) and ground-glass opacities (16%). A higher prevalence of nodules suggestive of multifocal micronodular pneumocyte hyperplasia (MMPH), ground-glass opacities and sclerotic bone lesions was found in the TSC-LAM group (table 5 and figure 3).

#### Discussion

The natural history and clinical course of S-LAM and TSC-LAM are not completely understood, particularly whether the latter represents a less severe phenotype. Our study provides valuable information by comparing S-LAM and TSC-LAM in a unique Latin American cohort, with an emphasis on the annual rate of change in lung function. The main findings of our study were as follows: 1) Patients with S-LAM presented higher annual rates of lung function decline, which did not appear to be related to age, baseline severity or use of mTOR inhibitors, according to our findings; 2) functional features were similar between

**FIGURE 2** High-resolution computed tomography (CT) of the chest images of patients with LAM show multiple and regular thin-walled pulmonary cysts. Cysts are depicted in blue and represent areas with voxels with an attenuation of  $-950$  HU or lower. a) Axial and b) coronal CT scans demonstrate few scattered cysts occupying 0.20% of the total lung volume. c) Axial and d) coronal CT scans show diffuse pulmonary cysts occupying 9.41% of the total lung volume.

the two groups; 3) there were no differences in thoracic and extrathoracic clinical manifestations between the two groups, except for a higher prevalence of lung ground-glass opacities, nodules suggestive of MMPH, sclerotic bone lesions, renal angiomyolipoma, and neurological and dermatological features in TSC-LAM; 4) the main indication for treatment with mTOR inhibitors was lung function decline in S-LAM and renal angiomyolipoma in TSC-LAM; 5) lower lung cyst extensions on CT scan were observed in TSC-LAM; and 6) patients with TSC-LAM seem to suffer a greater impact on vitality and emotional health.

In accordance with previous studies, reduced  $D_{LCO}$ , air trapping and obstructive patterns were the most common functional abnormalities identified in our study, with no significant differences between S-LAM and TSC-LAM [14, 31]. The S-LAM group presented with a lower  $FEV_1/FVC$  ratio and higher TLC, suggesting higher obstruction and hyperinflation in this population. Previous studies have demonstrated lower functional impairment in TSC-LAM, with higher levels of  $FEV_1$  and  $D_{LCO}$  compared to S-LAM, which was not confirmed in our study [14, 16].

Patients with S-LAM presented a higher annual rate of  $FEV_1$  decline than patients with TSC-LAM, which was not related to age, baseline  $FEV_1$  or the use of mTOR inhibitors. As patients with TSC-LAM presented a higher proportion of mTOR inhibitor use than those with S-LAM (63% versus 25%,  $p=0.002$ ), we performed an additional analysis accessing only those not treated with sirolimus, and obtained similar results. A few studies have compared the  $FEV_1$  slope between S-LAM and TSC-LAM, and observed no

TABLE 5 Chest CT variables obtained at the study inclusion

	LAM	Sporadic LAM	TSC-LAM	p-value
Patients n	97	69	28	
Extension of cysts % <sup>#</sup>	3.8 (0.9–13.4)	5.1 (1.2–13.6)	1.2 (0.2–7.8)	0.027
<b>Other thoracic findings</b>				
Nodules suggestive of MMPH	12 (12)	1 (1)	11 (39)	<0.001
Ground-glass opacities	16 (16)	5 (7)	11 (39)	<0.001

Values are expressed as median (25th–75th percentile) or n (%). CT: computed tomography; LAM: lymphangioliomyomatosis; TSC: tuberous sclerosis complex; MMPH: multifocal micronodular pneumocyte hyperplasia. <sup>#</sup>: n expressed in each column, respectively: 92 (total), 66 (S-LAM) and 26 (TSC-LAM); 15 patients from the initial sample were not included in the lung cysts quantification due to technical limitations on importing and/or processing the images by the software (seven) or unavailability of the chest CT images (eight).

**FIGURE 3** a) Axial thoracic computed tomography (CT) image shows ground-glass opacities associated with diffuse lung cysts (green arrows); b) axial thoracic CT images demonstrates lymphangioliomyoma (green arrow); c) abdominal CT image shows left renal angiomyolipoma (green arrow) in a patient with previous right nephrectomy; d) axial thoracic CT scan demonstrates noncalcified nodules (green arrows) suggestive of multifocal micronodular pneumocyte hyperplasia associated with diffuse lung cysts.

differences [12, 15, 16, 19]. The National Heart, Lung and Blood Institute (NHLBI) group demonstrated that, although there was no difference in FEV<sub>1</sub> decline between the S-LAM and TSC-LAM groups matched for age and PFTs, a greater proportion of patients with S-LAM presented higher rates of FEV<sub>1</sub> decline [16]. Additionally, the annual rates of functional decline in our population were lower than those observed in previous studies, possibly because of the higher proportion of patients treated with mTOR inhibitors. Although the estimated number of patients with TSC-LAM exceeds those with S-LAM, the latter usually constitute the majority in reference centres, which is similar to our findings, and commonly require medical interventions [6, 17, 32, 33]. This finding may explain the difference observed in the functional decline in our study. Moreover, we cannot rule out a lead time bias due to preconised screening of LAM in patients with TSC.

Other studies have demonstrated various predictors of greater functional decline and disease severity, such as lower baseline FEV<sub>1</sub>, reduced  $D_{LCO}$ , dyspnoea, desaturation during the 6MWT and cystic extension [13, 15, 34]. In our study, the occurrence of pneumothorax, desaturation during the 6MWT and extent of lung cysts were the predictors of functional impairment.

Evaluation of lung cyst extension using semi-quantitative or quantitative methods has been used to assess disease severity with a good correlation with PFTs [13, 35]. Some authors analysed and compared the extent of pulmonary cysts between the S-LAM and TSC-LAM, and reported varying results. AVILA *et al.* [32] demonstrated less severe lung disease in the TSC-LAM group, whereas other authors found no significant differences between the two groups [16, 36]. Our study showed mild cystic involvement and a higher extent of lung cysts in patients with S-LAM. We observed a higher prevalence of nodules suggestive of MMPH in the TSC-LAM group. Moreover, in contrast to other reports, patients with TSC-LAM presented a higher prevalence of ground-glass opacities, which may represent alveolar haemorrhage or lymphatic congestion [36]. Contrary to previous studies [32], we demonstrated a similar prevalence of lymphatic abnormalities between the two groups, including pleural effusion, and thoracic lymphadenopathy.

Renal angiomyolipomas were the most common extrathoracic findings in our study, with a higher prevalence in TSC-LAM, similar to previous reports [6, 14]. Additionally, previous nephrectomies were more frequent in this group. Angiomyolipomas may increase in size, causing pain and haemorrhage, which may contribute to morbidity and a higher risk of death [4, 37]. Previous studies have demonstrated that LAM is associated with reduced quality of life [14, 38, 39]. Lower scores were found in all domains of the SF-36 questionnaire in patients with LAM compared to healthy Brazilian women paired for age, with worse scores in the domains of general health perception, vitality and mental health [40]. In our study, patients with TSC-LAM demonstrated lower emotional health and vitality scores than those with S-LAM, which may be associated with a higher prevalence of extrapulmonary manifestations. This finding differs from the results of the NHLBI LAM registry, which showed no difference in SF-36 scores between these groups [14]. Our findings suggest that multidisciplinary care and holistic management plans should be provided to patients with LAM.

This study has several limitations. First, the retrospective design was an expected limitation, considering the rarity of the disease. Second, data were obtained from routine clinical follow-ups of the patients, which may explain the occurrence of missing data. Third, some patients were diagnosed close to the time of data collection and not all patients were included in the analysis of the rate of FEV<sub>1</sub> decline. Even with these missing data, we could demonstrate the difference between the slopes of the S-LAM and TSC-LAM. Finally, we cannot exclude the possibility that the higher prevalence of mTOR inhibitors in patients with TSC-LAM affected the differences in the rates of FEV<sub>1</sub> decline observed between the two groups. However, this hypothesis is less likely because we performed an analysis only including patients not treated with mTOR inhibitors, and obtained similar results. Although this was a single-centre study and biases associated with institutional practices should be considered when extrapolating these findings to other LAM populations, our cohort is representative of the whole country, as patients from different regions are referred to our centre.

To the best of our knowledge, this is the first study to describe a faster rate of functional decline in patients with S-LAM than in those with TSC-LAM. Higher obstruction and hyperinflation as well as a greater extent of lung cystic destruction were demonstrated in patients with S-LAM. The quality of life in patients with TSC-LAM showed greater impairment due to lower emotional health and vitality scores, which may be related to the extrapulmonary manifestations of the disease. As the largest LAM cohort in Latin America, our study provides a valuable and broad clinical, functional and tomographic characterisation of patients with LAM, contributing to a better understanding of the differences between the two forms of the disease.

Provenance: Submitted article, peer reviewed.

Conflict of interest: None declared.

Ethics statement: This study involved patients who were submitted to clinical, tomographic and functional evaluation. All patients have signed the informed consent and the study protocol was approved by the local research ethics committee.

Support statement: Financial support for this study was provided by Novartis Biociências SA. Novartis had no participation in the design, management, analysis of the data or in the decision to publish this study. Funding information for this article has been deposited with the Crossref Funder Registry.
