Background: The relationship between changes in the left atrial volume index (LAVI) post-catheter ablation (CA) and long-term prognostic events in patients with persistent atrial fibrillation (AF) remains unclear. We evaluated the incidence of major adverse clinical events (MACE), including all-cause death, unplanned heart failure hospitalization, and unplanned cardiovascular hospitalization using pre- and post-CA LAVI.

Methods and Results: We collected data retrospectively from 150 patients with persistent AF who underwent their first CA. LAVI was calculated during preprocedural echocardiography under AF rhythm (pre-CA LAVI) and 3 months post-CA under sinus rhythm (post-CA LAVI). The cumulative incidence of MACE was compared among 3 subgroups based on the cutoff values of pre-CA (45.5 mL/m^2) and post-CA (46.5 mL/m^2 ; both determined using the c-statistic) LAVI. The subgroup of a pre-CA LAVI $>45.5 \text{ mL/m}^2$ with a post-CA LAVI $>46.5 \text{ mL/m}^2$ ($n=45$) had a significantly higher MACE incidence compared with other subgroups ($P=0.002$). Multivariate analysis identified this subgroup as independently at higher risk for MACE. The subgroup of a pre-CA LAVI $>45.5 \text{ mL/m}^2$ with a post-CA LAVI $\leq 46.5 \text{ mL/m}^2$ ($n=49$) had an incidence comparable with those with pre-CA LAVI $\leq 45.5 \text{ mL/m}^2$ ($n=56$) and exhibited a significantly greater reduction in LAVI than other subgroups did ($P<0.001$).

Conclusions: Combining pre-CA and post-CA LAVIs is valuable in stratifying long-term MACE development risk following CA.

Key Words: Atrial fibrillation; Catheter ablation; Heart failure; Left atrial volume index; Major adverse clinical events

Left atrial (LA) enlargement, a hallmark of maladaptive deterioration in patients with atrial fibrillation (AF), is commonly referred to as “LA remodeling”.^{1–3} This change is frequently observed with the progression of AF, particularly in the transition from paroxysmal to persistent AF, characterized by LA volume expansion.³ LA remodeling is closely linked to an elevated risk of critical events such as worsening heart failure (HF) and stroke.⁴ Hence, it is rational to explore therapies aimed at mitigating this remodeling with the expectation of improving the long-term prognosis.^{1,4}

Catheter ablation (CA) for AF has emerged as a primary therapeutic option because of its superior ability to restore sinus rhythm with a high safety profile compared with pharmacological therapy.⁵ Additionally, CA has been reported to be effective in reversing LA remodeling and impeding AF progression.^{5–7} Although previous studies have suggested a potential association between reverse LA remodeling and a reduced risk of arrhythmic recurrence, there remains a paucity of information regarding the prognostic events following CA.^{6–8} Previously we reported a strong association between atrial tachyarrhythmia recurrence and the

incidence of prognostic events, especially heart failure hospitalization (HFH), in patients undergoing CA for AF.⁹⁻¹¹

Considering that patients who experience reverse LA remodeling after CA for AF tend to demonstrate lower risks of arrhythmic recurrence, it is conceivable that they may also encounter fewer clinical events, particularly HFH. In addition, investigations focusing on the LA volume before and after the restoration of sinus rhythm by CA could provide better selection for stratifying long-term prognostic risks.

To comprehensively address this clinical inquiry, we assessed the association between LA volume before/after CA and the incidence of major adverse clinical events (MACE) during a long-term follow-up period in patients with persistent AF who underwent CA at Yamaguchi University Hospital. The present study aimed to explore the clinical utility of LA volume pre- and post-CA in stratifying the risk of long-term MACE.

Methods

Study Outline

This was a single-center historical cohort study. The study was approved by the ethics committee of Yamaguchi University Hospital. The requirement for informed consent was waived because an opt-out system was used. The study followed the principles outlined in the Declaration of Helsinki and the ethical standards established by the Committee on Human Experimentation.

We collected retrospective data on patients with persistent AF who underwent CA between January 2010 and December 2020 at Yamaguchi University Hospital. Among these patients, we assessed those who maintained AF rhythm at preoperative echocardiography and restored sinus rhythm at echocardiography 3 months after CA. Persistent AF was defined as episodes that lasted longer than 7 days.^{2,12}

Patients for whom echocardiography information, particularly the left atrial volume index (LAVI; with LA volume corrected for body surface area), was unavailable were excluded. In addition, those who only had echocardiography data with a mismatched rhythm (e.g., sinus rhythm at pre-CA or AF rhythm at post-CA) were also excluded.

Study Design

We divided the entire cohort of patients who achieved restoration of sinus rhythm into subgroups based on 3 different cutoff criteria for LAVI values: 1 using solely pre-CA LAVI values (2 subgroups); 1 using solely post-CA LAVI values (2 subgroups); and 1 using both pre-CA and post-CA LAVI values (3 subgroups). The incidences of endpoints among these subgroups were then compared.

Study Endpoints

The primary endpoint was the MACE incidence following CA. As mentioned in our previous studies,^{9,11} MACE represents a composite endpoint, including all-cause death (ACD), HFH, and cardiovascular hospitalization (CVH). HFH refers to an unplanned hospitalization for the treatment of decompensated HF, whereas CVH refers to an unexpected hospitalization for the treatment of cardiovascular diseases other than HF. Events that occurred during the blanking period (within 3 months of the initial procedure) were excluded.

In terms of the secondary endpoint, we compared the

extent of reduction in LAVI between pre- and post-CA, and other demographic parameters among the subgroups. We also compared the cumulative incidence of arrhythmic recurrence among the subgroups. In addition, we assessed the utility of the combination of cutoff values of LAVI for discriminating the risk of MACE incidence, using multivariate analysis to adjust for confounding factors.

CA Procedure and Follow up

During the study period, our procedural strategy for persistent AF focused on treating the triggers for AF (i.e., pulmonary vein isolation and superior vena cava isolation using radiofrequency energy or second-generation cryoballoon energy), as described in our previous studies.¹¹ Patients with clinically diagnosed or induced atrial flutter/tachycardias underwent additional ablation to specifically target those arrhythmias.

After the procedure, all patients underwent ambulatory follow up. Echocardiography was performed mandatorily 3 months after the procedure. Arrhythmic recurrence was defined as atrial tachyarrhythmia lasting longer than 30 s after the blanking period. The success rate was defined as the proportion of patients free from arrhythmic recurrence at a specified time. If patients experienced a recurrence of atrial tachyarrhythmia, a repeat procedure was scheduled unless the patient refused. Data regarding clinical events were obtained by asking the primary care physician about each patient in December 2021.

Echocardiography Evaluation

Our echocardiography protocol was performed in accordance with the American Society of Echocardiography's guidelines.¹³ The LAVI was calculated by combining images obtained from the apical 2- and 4-chamber views. Patients with poor images were substituted using only an apical 4-chamber view. The definition of "severely dilated" LA was set as $>40 \text{ mL/m}^2$, as per guidelines.¹³ The AF rhythm was calculated from the index beat. The extent of reduction in LAVI was calculated as follows: $([\text{Post-CA LAVI} - \text{Pre-CA LAVI}] / \text{Pre-CA LAVI} * 100)$.

Cutoff Values for LAVI

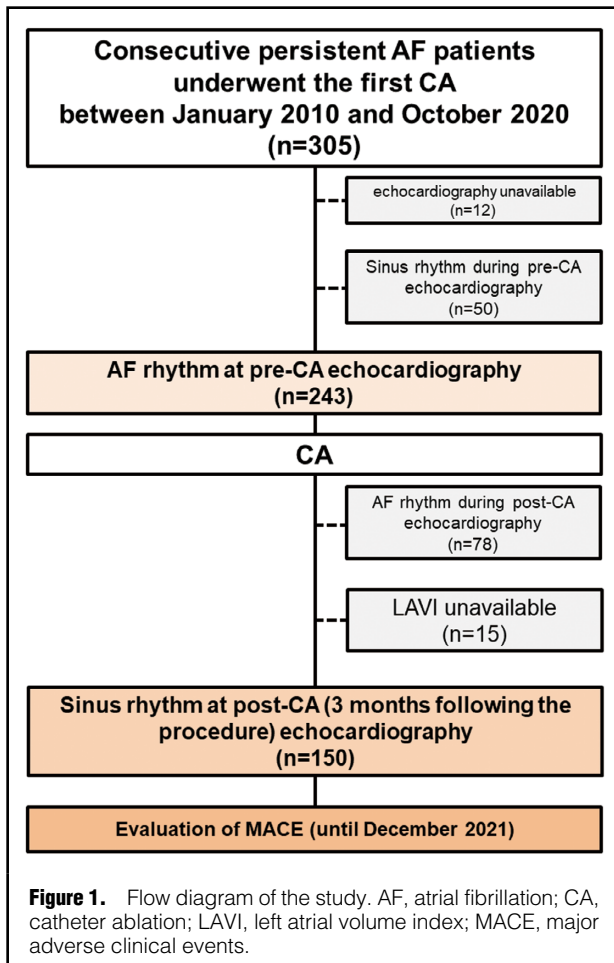

We determined the cutoff values for both pre-CA and post-CA LAVI using the c-statistic. The value with the maximum area under the curve (AUC) in the receiver operating characteristic curve was set as the cutoff value.

Statistical Analysis

Normally and non-normally distributed variables were expressed as mean \pm SD and medians with interquartile ranges (first and third quartiles), respectively.

Differences in continuous variables between pre- and post-CA state were evaluated using the Wilcoxon signed-rank test. Differences in categorical variables were evaluated using the McNemar test. Differences in the reduction of LAVI among the 2 and 3 subgroups were evaluated using the Wilcoxon rank-sum test, and an analysis of variance, respectively.

Differences in demographic parameters among the subgroups were compared using analysis of variance. When conducting post-hoc pairwise comparisons between 2 of the 3 groups, a t-test was used for normally distributed data, a Wilcoxon test for non-normally distributed data, and a chi-square test for categorical data, with Bonferroni correction applied.

The incidence of each event and arrhythmic recurrence was expressed as the cumulative incidence with a 95% confidence interval (CI) calculated at the median follow up. The log-rank test was used to compare the cumulative incidence among the subgroups. A c-statistic was performed to compare the discrimination ability for the development of MACE between using solely pre-CA LAVI and the combination of pre- and post-CA LAVI. The difference was compared using the DeLong test.

For the univariate and multivariate analysis, factors associated with the development of long-term adverse events in HF patients were selected as variable.^{9-11,14} We applied a stepwise approach in the multivariate analysis, imputing variables with a P value <0.05 from the univariate analysis. The continuous variables used in the analysis were dichotomized according to conventional cutoff points. The findings are presented as hazard ratios and 95% CIs. Statistical analyses were conducted using R version 4.3.2, and the results were considered statistically significant at a P value <0.05, except for post-hoc pairwise comparisons with Bonferroni correction, where a significance level of 0.017 was used.

Results

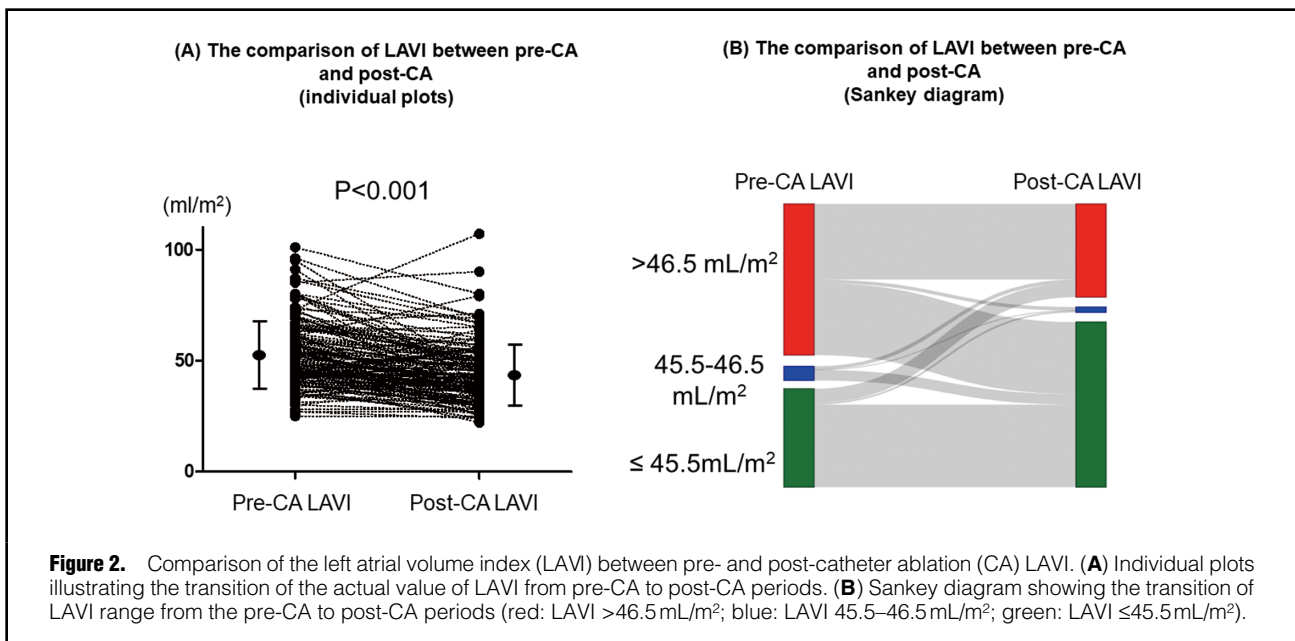

Study Population

A flow diagram of the study protocol is illustrated in **Figure 1**. Among the 305 patients with persistent AF who

Numerical data are expressed as mean±SD or median (interquartile range [IQR]; first quartile–third quartile). Categorical data are expressed as n (%). AADs, antiarrhythmic drugs; ACEI, angiotensin-converting enzyme inhibitor; AF, atrial fibrillation; ARB, angiotensin II receptor blocker; BMI, body mass index; BNP, B-type natriuretic peptide; CAD, coronary artery disease; CCB, calcium channel blocker; CRT, cardiac resynchronization therapy; CTI, cavotricuspid isthmus; CTR, cardiothoracic ratio; DCM, dilated cardiomyopathy; DHCM, dilated phase of hypertrophic cardiomyopathy; DM, diabetes mellitus; eGFR, estimated glomerular filtration rate; HCM, hypertrophic cardiomyopathy; HFH, heart failure hospitalization; ICD, implantable cardioverter-defibrillator; LA, left atrium; MRA, mineralocorticoid receptor antagonist; PVI, pulmonary vein isolation; SD, standard deviation; SVC, superior vena cava; VHD, valvular heart disease.

underwent CA, 243 underwent pre-CA echocardiography for AF rhythm. All patients underwent CA successfully. Of these, 150 patients were included in the present study. Patient demographics are presented in **Table 1**. The success rates were 87% and 79% at 6 months and 1 year after the first procedure, respectively. Among patients who experienced atrial tachyarrhythmia recurrence, a median of 1.0 (0.5, 1.0) additional procedure was performed. The success

rates following the last procedure were 92% (6 months) and 88% (1 year), and 90% (6 months) and 82% (1 year) were no longer taking antiarrhythmic drugs.

Change of Echocardiography and Associated Parameters Between Pre- and Post-CA Periods

Supplementary Table 1 presents a comparison of the echocardiography and associated parameters between the pre- and post-CA periods. In general, systolic blood pressure increased significantly, with a significant reduction in heart rate following CA. The left ventricular ejection fraction also increased significantly. The LAVI reduced significantly after the procedure ($53 \pm 15 \text{ mL/m}^2$ vs. $44 \pm 14 \text{ mL/m}^2$; $P < 0.0001$; **Figure 2A**).

Figure 2B illustrates the changes in LAVI between the pre- and post-CA periods. Although most patients had a severely dilated LA (LAVI >40 mL/m²) in the pre-CA period, the proportion was significantly decreased in the post-CA period (121/150 [81%] vs. 78/150 [52%] patients; $P < 0.0001$).

MACE Incidence and the Cutoff Value for Pre- and Post-CA LAVI

During the entire follow-up period (median 4.1 [2.8, 5.7] years), 16 patients developed at least 1 MACE. Of those events, HFH accounted for the majority (18/28 [64%] events), followed by ACD (6/28 [21%] events) and CVH (4/28 [14%] events). A list of patient demographics is presented in **Supplementary Table 2**. Moreover, HFH was the first major adverse clinical event in 10 of 16 (63%) events. The c-statistic for discriminating MACE provided a cutoff value of 45.5 mL/m² with the highest AUC (0.66 [95% CI 0.53, 0.79]) for pre-CA LAVI, and 46.5 mL/m² (0.64 [95% CI 0.48, 0.78]) for post-CA LAVI.

Cumulative MACE Incidence Among the Subgroups

Figure 3 and **Table 2** compare the cumulative incidence of MACE among the subgroups based on the pre- and post-CA LAVIs. In the subgroup using solely pre-CA LAVI

values, the group with a pre-CA LAVI ≤45.5 mL/m² (n=56) had a significantly lower MACE incidence than did those with a pre-CA LAVI >45.5 mL/m² (n=94; 1.85% [0, 5.38] vs. 13.13% [6.00, 20.54]; $P = 0.007$; **Figure 3A**; **Table 2A**). The subgroup using solely post-CA LAVI values also followed the same trend: the group with a post-CA LAVI ≤46.5 mL/m² (n=53) had a significantly lower MACE incidence than did those with a post-CA LAVI >46.5 mL/m² (n=97; **Figure 3B**; **Table 2B**).

In contrast, the subgroups using both pre-CA and post-CA LAVI values showed a difference in MACE incidence among patients with a pre-CA LAVI of >45.5 mL/m². The group of pre-CA LAVI >45.5 mL/m² with post-CA LAVI >46.5 mL/m² (n=45) had a significantly higher incidence of MACE than did the other subgroups (22.01% [7.00, 34.79]; $P = 0.002$; **Figure 4**; **Table 2C**). The incidence of HFH also followed a similar trend ($P = 0.003$). The subgroup of pre-CA LAVI >45.5 mL/m² with post-CA LAVI ≤46.5 mL/m² (n=70) had an incidence of MACE comparable with that in the subgroup with a pre-CA LAVI ≤45.5 mL/m² (4.96% [0, 11.53]; **Table 2C**).

The c-statistic for the development of MACE indicated a higher tendency for discrimination ability when combining pre- and post-CA LAVI (AUC [95% CI] 0.71 [0.59, 0.83] for pre-CA LAVI >45.5 mL/m² with post-CA LAVI >46.5 mL/m² compared with using solely pre-CA LAVI (LAVI >45.5 mL/m²; $P = 0.440$) and solely post-CA LAVI (LAVI >46.5 mL/m²; $P = 0.003$).

Extent of Reduction in LAVI Among the Subgroups

Supplementary Figure 1 compares the reduction in LAVI among subgroups. The subgroup with a pre-CA LAVI >45.5 mL/m² showed a significantly greater reduction in LAVI compared with those with LAVI ≤45.5 mL/m² (pre-CA LAVI >45.5 mL/m²: -20.70% [-33.30, -10.50] vs. pre-CA LAVI ≤45.5 mL/m²: -8.20% [-19.00, 6.37]; $P < 0.001$; **Supplementary Figure 1A**). The subgroup based on a post-CA LAVI also followed the same trend (post-CA LAVI >46.5 mL/m²: -23.10% [-33.30, -10.00] vs. post-CA

among the 3 subgroups. The subgroup with pre-LAVI ≤ 45.5 mL/m² demonstrated a lower proportion of prior HFH and structural heart diseases, a higher estimated glomerular filtration rate, and lower levels of B-type natriuretic peptide compared with the other subgroups.

Within the subgroups with pre-CA LAVI >45.5 mL/m², the subgroup with post-CA LAVI ≤ 46.5 mL/m² exhibited a significantly lower proportion of females, lower levels of B-type natriuretic peptide, and lower pre-CA estimated pulmonary artery systolic pressure compared with the subgroup with post-CA LAVI >46.5 mL/m².

Regarding post-CA echocardiography parameters, the subgroup with post-CA LAVI ≤ 46.5 mL/m² showed a significantly lower E/e' ratio, lower estimated pulmonary artery systolic pressure, and a lower E/A ratio of transmitral flow compared with the subgroup with post-CA LAVI >46.5 mL/m². Interestingly, the post-CA LAVI and other echocardiography parameters in the subgroup were comparable with that in the subgroup with pre-CA LAVI ≤ 45.5 mL/m².

Difference of Arrhythmic Recurrence Among the Subgroups

We compared the cumulative incidence of atrial tachyarrhythmia among the 3 subgroups. At 1 year follow up after the first session, the incidence in the subgroup with a pre-CA LAVI >45.5 mL/m² with post-CA LAVI >46.5 mL/m² was significantly higher than other subgroups (pre-CA LAVI >45.5 mL/m² with post-CA LAVI >46.5 mL/m²: 35.56% [19.94, 48.13]; pre-CA LAVI >45.5 mL/m² with post-CA LAVI ≤ 46.5 mL/m²: 16.33% [5.31, 26.06]; pre-CA LAVI ≤ 45.5 mL/m²: 16.07% [5.88, 25.16]; P=0.030).

The difference was consistent following the last session (pre-CA LAVI >45.5 mL/m² with post-CA LAVI >46.5 mL/m²: 46.93% [24.71, 62.60]; pre-CA LAVI >45.5 mL/m² with post-CA LAVI ≤ 46.5 mL/m²: 15.80% [4.15, 26.04]; pre-CA LAVI ≤ 45.5 mL/m²: 16.31% [4.11, 26.96]; P<0.001).

Univariate and Multivariate Analysis for the Risk of Developing MACE

Table 4 presents the results of the univariate and multivariate analyses for the risk of developing MACE. The univariate analysis showed that a pre-CA LAVI >45.5 mL/m² with a post-CA LAVI >46.5 mL/m², prior HFH, and a B-type natriuretic peptide level >200 pg/mL (3 months after CA) were identified as the significant factors. The multivariate analysis identified a pre-CA LAVI >45.5 mL/m² with a post-CA LAVI >46.5 mL/m² as the only

independent factor associated with MACE development risk (adjusted hazard ratio [95% CI] 3.84 [1.24, 11.87]; P=0.019).

Discussion

Main Findings

The important findings of the present study are as follows (Supplementary Figure: Graphical Abstract). First, after the restoration of sinus rhythm due to CA, the reduction in LAVI after the procedure (53 ± 15 mL/m² vs. 44 ± 14 mL/m²) resulted in a marked decrease in the proportion of patients with severely dilated LA (LAVI >40 mL/m²) from 81% to 52% (121/150 vs. 78/150 patients; P<0.001). Second, the subgroup of a pre-CA LAVI >45.5 mL/m² with a post-CA LAVI >46.5 mL/m² had a significantly higher incidence of MACE than did the other subgroups; however, the subgroup of pre-CA LAVI >45.5 mL/m² with post-CA LAVI ≤ 46.5 mL/m² had a risk comparable with those with pre-CA LAVI ≤ 45.5 mL/m². Third, the extent of reduction in LAVI was significantly greater in the subgroup of pre-CA LAVI >45.5 mL/m² with post-CA LAVI ≤ 46.5 mL/m² (−31.40% [−43.00, −21.10]; P<0.001). Fourth, pre-CA LAVI >45.5 mL/m² with post-CA LAVI >46.5 mL/m² remained an independent factor associated with the risk of MACE development after multivariate adjustment.

Reverse LA Remodeling Following CA

Various stressors, such as deleterious hemodynamics, electrical abnormalities, and metabolic disorders, are believed to contribute to the mechanism of LA remodeling.^{14,15} Chronic exposure to these stressors may impair atrial compliance and foster a vicious cycle of LA remodeling. The LA remodeling can be characterized by the progression of late gadolinium enhancement, as demonstrated by a previous study using cardiac magnetic resonance imaging.¹⁶ Histologically, even patients with long-standing persistent AF exhibited degenerative changes such as fibrosis, increased intercellular space, and decreased myocardial nuclear density, representing LA remodeling.¹⁷ Furthermore, those findings showed a significant correlation with electrical changes, such as low-voltage areas and fractionated electrograms obtained from electroanatomic mapping.¹⁷

Although the progression of LA remodeling represents histological and electrical alterations, studies have suggested that reverse LA remodeling, characterized by a recovery in LA functions and a reduction in LA volume, can be observed following CA for AF in a certain proportion of

patients.^{7,8,18} Consistent with these findings, we novelly demonstrated that patients with pre-CA LAVI $>45.5 \text{ mL/m}^2$ and post-CA LAVI $\leq 46.5 \text{ mL/m}^2$ exhibited a greater extent of LA volume reversal and had a significantly lower incidence of long-term MACE than did those with pre-CA LAVI $>45.5 \text{ mL/m}^2$ and post-CA LAVI $>46.5 \text{ mL/m}^2$, even though both subgroups suggested a poor long-term MACE incidence based on criteria solely using preoperative LAVI. This finding is further supported by a recent study, which reported that patients with enlarged LAVI post-CA for AF faced a heightened risk of adverse events such as HFH, regardless of arrhythmic recurrence.¹⁹ Our result, indicating that post-CA LAVI is crucial for the risk of clinical events, aligns with the literature.

The mechanism behind the variation in the extent of reverse LA remodeling can be postulated to the difference in the underlying myocardial condition. In both the atria and ventricles, reverse remodeling can be expected in milder myocardial degeneration.²⁰ In cases of AF, findings suggestive of limited progression, such as a shorter history of AF, fewer symptoms, and a lack of myocardial fibrosis, have been reported as predictors of favorable remodeling after ablation.²¹ Furthermore, cases that exhibit favorable reverse LA remodeling can tend to involve the etiology where AF acts as a primary cause of the remodeling, similar to “arrhythmia-induced cardiomyopathy”.^{22,23} Conversely, cases with poor reverse LA remodeling may reflect an underlying myocardial dysfunction where AF is an epiphenomenon.²² In such scenarios, the benefit of the restoration of sinus rhythm would be limited, as AF represents a consequence of a progressive myocardial condition, such as atrial cardiomyopathy.²⁴ Our results may reflect the difference. Of note, the subgroup with poor reverse LA remodeling (post-CA LAVI $>46.5 \text{ mL/m}^2$) still demonstrated findings suggestive of increased left atrial pressure (higher E/e' , higher estimated pulmonary artery systolic pressure, and higher E/A ratio of trans-mitral flow) regardless of the restoration of sinus rhythm. Conversely, the subgroup with fair reverse LA remodeling (post-CA LAVI $\leq 46.5 \text{ mL/m}^2$) showed that these parameters were comparable with those in the subgroup without dilated LA, further supporting our inference.

Our population would contain patients with heterogeneous backgrounds as it consists of cases derived from clinical practice, making it difficult to thoroughly assess the differences in underlying myocardial conditions among subgroups based solely on LAVI in this study. However, the LAVI-related indicators obtained in this study would be considered useful for stratification in estimating prognostic events following CA. For a better understanding of the underlying mechanisms, qualitative evaluation of the altered atrial myocardial substrate using advanced modalities such as cardiac magnetic resonance and LA strain echocardiography is deemed useful. Although our results provide risk stratification information post-procedure only, further investigations using these modalities may offer valuable information pre-procedure.

Clinical Implications

Our investigation highlights the novel potential significance of integrating pre-CA and post-CA LAVI measurements to identify long-term MACE after CA in patients with persistent AF. Notably, patients exhibiting pre-CA LAVI $>45.5 \text{ mL/m}^2$ with post-CA LAVI $>46.5 \text{ mL/m}^2$ demonstrated a higher risk of developing long-term MACE. In

contrast, those with pre-CA LAVI $>45.5 \text{ mL/m}^2$ and post-CA LAVI $\leq 46.5 \text{ mL/m}^2$ had a level of risk comparable with those who suggested a fair prognosis based solely on the cutoff of pre-CA LAVI ($\leq 45.5 \text{ mL/m}^2$) and experienced a greater extent of reverse LA remodeling.

Generally, a dilated LA in patients is considered to impair the success rate for CA, which often leads to hesitation in choosing this treatment option.²² Despite having a dilated LA, patients who achieve greater reverse LA remodeling are likely to benefit from sinus rhythm restoration through CA greatly and thus represent ideal candidates for this procedure. We believe that the use of pre-CA and post-CA LAVI measurements can provide clinically useful insights regarding the effectiveness of CA in patients with persistent AF.

Study Limitations

Our study has some limitations. First, the retrospective collection of data solely from our institution, as part of a single-center historical cohort design, raises questions regarding the generalizability of the obtained cutoff values to other populations. Thus, validation at different institutions is essential. Second, our study design included only patients who achieved the restoration of sinus rhythm 3 months after CA. Considering the challenging success rate of CA for persistent AF in a single procedure, several patients were excluded due to recurrence, which potentially introduced selection bias into our study. Third, the process of reverse LA remodeling involves various factors beyond the restoration of sinus rhythm. For instance, medications for heart failure may be associated with LA reverse remodeling.^{25,26} Therefore, factors other than the restoration of sinus rhythm could have influenced the reverse remodeling observed in our study. Last, in the present study, we did not focus on the extent of reverse LA remodeling for risk stratification, but rather on pre-CA and post-CA LAVI. The combination of the extent of LA remodeling and post-CA LAVI may enable more practical stratification, and further research is needed.

Conclusions

Our findings showed that combining pre- and post-CA LAVI could facilitate the risk stratification of long-term MACE development following CA in patients with persistent AF.
