#### Abstract

**Objective:** The objective of the study was to assess the quality of root canal fillings of cases referred to endodontic surgery using preoperative radiographs and correlate it with endodontic surgery treatment decision. The objective was also to analyse clinical symptoms and size of periapical lesions on radiographs and correlate them with treatment decisions including non-surgical retreatment, endodontic surgery and extraction. **Material and Methods:** A questionnaire was composed to record the data. Eighty-six patients with 109 teeth, who were referred to endodontic surgery, participated in the research. The quality of root canal filling was assessed according to its homogeneity and filling length on digital radiographs. The data were analyzed using  $\chi^2$ -test and t-test. **Results:** Of the teeth referred to endodontic surgery, 97.2% were treated by a general practice dentist, endodontic retreatment was attempted in 20.6%, and root canal filling was homogeneous and within 1 mm from the apex in 21.6%. Endodontic surgery, retreatment, extraction and no treatment were selected in 90.1%, 5.4%, 1.8% and 2.7% of the cases, respectively. **Conclusions:** Low percentage of adequate root canal fillings and high percentage of endodontic surgery decisions suggest that there is a need to increase awareness of non-surgical retreatment options.

Decision Making; Dental Radiography; Endodontics; Endodontic Surgery; retreatment

## Introduction

The purpose of endodontic treatment is to preserve the function of a tooth with pathologically altered pulp, without harming patients' general health. According to the European Society of Endodontontology (ESE) and American Association of Endodontists (AAE) guidelines, the standard procedure includes cleaning, shaping, disinfection and sealing the root canals of the treated tooth (1, 2). The treatment is considered successful when clinical symptoms of periapical disease are absent and radiographic analysis confirms the healing of a periapical lesion (3, 4).

According to the literature, 14-16% of primary endodontic treatments result in failure (5). If radiographic and clinical findings indicate failure, three therapeutic options should be considered: non-surgical retreatment, endodontic surgery (including root-end resection and retrograde cavity filling) or tooth extraction (1, 6). The most frequent cause of failure is persistent infection in the root canal system and/or in periradicular area (7, 8). Other possible reasons include periradicular true cyst, accumulation of endogenous cholesterol crystals

## Uvod

Svrha endodontskog postupka jest očuvati funkciju zuba s patološki promijenjenom pulpom, a da se ne ugrozi pacijentovo opće zdravlje. Prema preporukama Europskoga endodontskog društva (engl. European Society of Endodontontology – ESE) i Američke endodontske udruge (engl. American Association of Endodontists – AAE) standardni endodontski postupak uključuje čišćenje, širenje, dezinfekciju i punjenje korijskih kanala (1, 2). Postupak se smatra uspješnim ako nema kliničkih simptoma periapikalne bolesti i kada radiološka analiza potvrđuje cijeljenje periapikalne lezije (3, 4).

Prema literaturi, od 14 do 16 % primarnih endodontskih liječenja rezultira neuspjehom (5). Ako klinički nalaz i radiogram upućuju na neuspjeh, treba razmotriti tri terapijske mogućnosti – konzervativnu reviziju liječenja, endodontsku kirurgiju (uključujući resekciju vrška korijena i retrogradno punjenje) ili ekstrakciju zuba (1, 6). Najčešći uzrok za neuspjeh je trajna, perzistentna infekcija u sustavu korijskih kanala i ili u periradikularnom području (7, 8). Ostali mogući razlozi uključuju periradikularne prave ciste, akumula-

in periapical tissue and foreign body reaction due to a root canal overfilling or cellulose-containing materials extruded during treatment (7, 9). When there is residual intraradicular infection, procedural mistakes such as short filling or overfilling, perforations of root canal wall and separated instrument could lead to failure (8, 10).

In the endodontic surgery procedure root tip is surgically removed together with the inflammatory process around it and retrograde cavity prepared and filled (1, 2). Endodontic surgery is indicated when periapical lesions persist and root canal system cannot be adequately cleaned and sealed due to developmental anomalies or iatrogenic causes or when the retreatment would compromise the tooth, e.g. the removal of the intracanal post. Furthermore, endodontic surgery needs to be performed if there is a suspicion of perforation or fracture in the root's apical third, when histopathological analysis is required and when retreatment is not possible due to the patient related reasons (1, 2, 11). Cohn et al. (12) reported that the success rate of surgical endodontics was 64%, which is considerably lower than the reported success rate of retreatments (80%) (13). Also, undesirable consequences of this surgical procedure are gingival recessions, scars and reduced resistance to occlusal forces and periodontal diseases due to root shortening (14, 15). It is, therefore, crucial that the indications for endodontic surgery are met and that each case is individually assessed (14, 15, 16). In the cases where neither retreatment nor endodontic surgery would enable inflammation regression and healing, tooth extraction is the treatment of choice (1).

It has been shown that the unsatisfactory quality of primary root canal fillings with inadequate length and homogeneity of the filling often leads to the development of a periapical process (17). An insufficient awareness of the etiology of persistent endodontic diseases and treatment possibilities leads to the increased referral to endodontic surgery (18).

According to the available literature, firm guidelines for failed root canal treatment seem to lack, and information about treatment decisions (orthograde retreatment vs. surgical treatment vs. extraction- implants) is modest (12, 18). The aim of this research was to determine the connection between the quality of root canal filling, symptoms, status of the tooth and surrounding tissues (clinical and radiographic) and treatment decision. The hypothesis was that endodontic surgery was the treatment of choice in the majority of the referred cases.

## Material and methods

The study was conducted in surgical infirmaries and operating rooms at the Department of Oral Surgery, School of Dental Medicine, University of Zagreb and the Clinical Department of Oral Surgery, Clinical Hospital Dubrava, Zagreb from January to April 2017. The research has been conducted in accordance with the World Medical Association Declaration of Helsinki, and The Ethics Committee of the School of Dental Medicine, University of Zagreb approved the research and the consent procedure. The written consent was obtained from all the participants who were older than 18, and from the parents of the participants that were under 18 years of age.

ciyu endogenih kolesterolskih kristala u periapikalnom tkivu i reakciju na strano tijelo zbog prepunjena ili ekstruzije celuloznih materijala u periapeks tijekom liječenja (7, 9). Kada postoji rezidualna intraradikularna infekcija, proceduralne pogreške, poput kratkog punjenja ili prepunjena perforacija korijena i separacije instrumenta, mogu rezultirati neuspjehom (8, 10).

U slučaju endodontsko-kirurškog zahvata, vršak korijena kirurški se uklanja (apikotomira) zajedno s upalnim područjem oko njega te se preparira i puni retrogradni kavitet (1, 2). Endodontska kirurgija indicirana je kada periapikalne lezije perzistiraju, a sustav korijenskih kanala ne može se adekvatno očistiti i zabrtviti zbog razvojnih anomalija ili iatrogenih uzroka ili u slučaju da ortogradna revizija ugrožava Zub, na primjer, kada je potrebno ukloniti intrakanalnu nadogradnju. Dodajmo da endodontsko-kirurški zahvat treba obaviti ako se sumnja da je apikalna trećina korijena perforirana ili frakturirana, kada je potrebna patohistološka analiza te kada revizija nije moguća zbog razloga vezanih za pacijenta (1, 2, 11). Cohn i suradnici (12) istaknuli su da je postotak uspješnosti endodontske kirurgije 64 %, što je značajno manje od postotka uspješnosti revizije liječenja (80 %) (13). Nadalje, nepoželjne posljedice ovoga kirurškog postupka su gingivna recesija, ožiljci, smanjena otpornost na okluzalne sile i parodontne bolesti zbog skraćenog korijena (14, 15). Zato je vrlo važno uzeti u obzir indikacije za endodontsku kirurgiju i procijeniti individualno svaki slučaj (14, 15, 16). U slučaju kada ni revizija, ni endodontska kirurgija ne mogu spriječiti regresiju upale i cijeljenje, ekstrakcija zuba je postupak izbora (1).

Pokazalo se da punjenja korijenskih kanala neadekvatne dužine i homogenosti često završavaju pojavom periapikalnih procesa (17). Nedovoljna svijest o etiologiji perzistentne endodontske bolesti i mogućnosti liječenja, uzrok je povećanog postotka upućivanja pacijenata na endodontsko-kirurški zahvat (18).

Prema dostupnoj literaturi, čvrste preporuke za neuspješno endodontsko liječenje ne postoje, a skromne su informacije i o terapijskim odlukama (ortogradna revizija liječenja vs. kirurška terapija vs. ekstrakcija – implantati) (12, 18). Svrha ovog istraživanja bila je povezati kvalitetu punjenja korijenskog kanala, simptome, status zuba i okolnih tkiva (klinički i radiološki) s odlukom o terapijskom postupku. Hipoteza je glasila da je za većinu upućenih pacijenata endodontsko-kirurški postupak bio terapijski postupak izbora.

## Materijali i metode

Istraživanje je provedeno u kirurškim ambulantama Zavoda za oralnu kirurgiju Stomatološkog fakulteta Sveučilišta u Zagrebu i Kliničkog odjela za oralnu kirurgiju Kliničke bolnice Dubrava u Zagrebu, od siječnja do travnja 2017. Obavljen je u skladu s Helsinškom deklaracijom Svjetske medicinske udruge, a odobrilo ga je Etičko povjerenstvo Stomatološkog fakulteta Sveučilišta u Zagrebu. Svi pacijenti stariji od 18 godina te roditelji onih mlađih od 18 godina, potpisali su informirani pristanak.

Prije istraživanja dvije su istraživačice (B. B. i J. B.) za procjenu uskladile kliničke i radiološke dijagnoze. Kriteriji

Prior to the research, two researchers (BB and JB) were calibrated for estimating clinical and radiographic diagnosis. The criteria for the assessment of clinical and radiographic findings were harmonized by analysing 51 digital retroalveolar and panoramic radiographs from the School of Dental Medicine, University of Zagreb database, recorded using Minray (for intraoral) and Cranex 3D Ceph (for orthopantomograms) X-ray machines and Scanora software (Soredex, Tuusula, Finland). The analyses were compared, and high degree of congruence was noticed. The results which did not match were processed and discussed and a 100% congruence was achieved.

Eighty-six patients referred to endodontic surgery participated in the study. Only the patients who signed the informed consent were included, and their anonymity was guaranteed. Clinical and radiographic finding, the decision of an oral surgery specialist about further procedure and intraoperative findings were recorded for each case. Dental history included data about previous procedures on the tooth and pain assessment. Clinical examination included tooth and soft tissue inspection. A radiographic analysis was conducted on panoramic ( $n=2$ ) and intraoral ( $n=101$ ) radiographs which included the assessment of homogeneity and filling length with respect to the radiographic apex, the presence of a separated instrument in root canal and the presence of perforation (19), the length and type of posts and the size of periapical transparency. When endodontic surgery was indicated, intraoperative findings of bone fenestration, dehiscence or vertical fracture of a tooth was recorded. The radiographs were made and analyzed using Minray and Cranex 3D Ceph machine (Soredex, Tuusula, Finland) and Scanora software (Soredex, Tuusula, Finland).

Cases referred to endodontic surgery for the first time and cases referred to repeated endodontic surgery were joined in one sample. When analyzing the data of patients that had multiple teeth referred for apicoectomy, each tooth was observed and analyzed individually.

The relationships between radiographically estimated quality of root canal filling (according to homogeneity and filling length), clinical and radiographic variables, variables from dental history and decision about the procedure were statistically analyzed. The  $\chi^2$ -test was used for the analysis of discrete variables and t-test for continuous variables ( $p < 0.05$ ). The analysis was done using SAS statistical package on Windows platform.

## Results

Out of 86 patients that participated in the study, 59.5% were female and 40.5% of them were male. More cases were evaluated in the operating room than in the surgical infirmary (3.8:1). There were no statistical differences between males and females for any variable ( $p>0.05$ ). Patients' average age was 44.4 years (14-81 years). Out of 106 analyzed teeth, 97.2% were treated by a general practice dentist. Endodontic retreatment before referring to endodontic surgery was performed in 20.6% of cases. The most common treatment selection was endodontic surgery (90.1%), while retreatment

za procjenu kliničkoga i radiološkog nalaza uskladeni su analiziranjem 51 digitalne retroalveolarne i panoramske snimke iz baze snimaka Stomatološkog fakulteta Sveučilišta u Zagrebu učinjenih uređajima Minray (za intraoralne) i Cranex 3D Ceph (za ortopantomografe) te obrađenih softverom Scanora (Soredex, Tuusula, Finska). Analize su uspoređene te je postignut visok stupanj podudarnosti. Rezultati koji se nisu podudarali analizirani su i o njima se raspravljalo te je postignuta podudarnost u 100 % slučajeva.

U istraživanju je sudjelovalo 86 pacijenata upućenih na endodontsko-kirurški zahvat (apikotomiju). Samo su oni koji su potpisali informirani pristanak sudjelovali u istraživanju, a anonimnost je bila zajamčena. Klinički i radiološki nalaz, odluka specijalista oralne kirurgije o dalnjem postupku te intraoperativni nalaz, zabilježeni su za pojedini slučaj. Dentalna anamneza uključivala je podatke o ranijim postupcima na zubu i procjenu boli. Klinički pregled uključivao je inspekciju zuba i okolnih mekih tkiva. Radiološka analiza učinjena je na ortopantomogramima ( $n = 2$ ) i intraoralnim radiogramima ( $n = 101$ ) te je obuhvaćala procjenu homogenosti i duljine punjenja prema radiološkom apeksu, prisutnost separiranog instrumenta u korijenskom kanalu i perforaciju korijena (19), duljinu i vrstu nadogradnje te veličinu peripikalne transparencije. Ako je bio indiciran endodontsko-kirurško zahvat, zabilježen je intraoperativni nalaz fenestracije kosti, dehiscencija ili vertikalna fraktura. Radiografi su snimljeni i analizirani uređajima Minray i Cranex 3D Ceph (Soredex, Tuusula, Finska) te softverom Scanora (Soredex, Tuusula, Finska).

Slučajevi koji su prvi put upućeni na endodontsko-kirurški zahvat te oni upućivani više puta, spojeni su u jedan uzorak. Kod pacijenta upućenih zbog dvaju ili više zuba, svaki je zub promatrano i analiziran posebno.

Statistički su analizirani odnosi između radiološki procijenjene kvalitete punjenja korijenskog kanala (prema homogenosti i duljini punjenja), kliničkih i radioloških varijabli, varijabli iz dentalne anamneze i odluke o postupku.  $\chi^2$ -test korišten je u analizi diskretnih varijabli, a t-test kontinuiranih varijabli ( $p < 0,05$ ). Analiza je obavljena u statističkom paketu SAS na platformi Windowsa.

## Rezultati

Među 86 pacijenata koji su sudjelovali u istraživanju, 59,5 % bile su žene, a 40,5 % muškarci. Više slučajeva analizirano je u operacijskoj dvorani, negoli u ambulantni (3,8 : 1). Nije bilo statistički značajnih razlika među spolovima ni za jednu varijablu ( $p > 0,05$ ). Prosječna dob pacijenta bila je 44,4 godine (14 – 81 godinu). Od 106 analiziranih zuba, 97,2 % tretirao je primarni liječnik dentalne medicine. Revizija endodontskog liječenja prije dolaska na endodontsku kirurgiju učinjena je u 20,6 % slučajeva. Najčešći odabrani postupak bio je endodontsko-kirurški (90,1 %), a revizija (5,4

(5.4%), not doing any procedure (2.7%) and extraction (1.8%) were less frequently selected. The majority of the examined teeth were upper incisors (66%). Most of the teeth were prosthetically reconstructed (62.9%) and more than half (53.5%) were supplied with an intracanal post (Table 1).

Root canal filling was homogeneous and within 1 mm from the apex in 21.6% of cases, while in 78.4% of cases filling was unsatisfactory according to either length or homogeneity. Considering all the variables and the homogeneity of filling (homogeneous or non-homogeneous), a statistically significant difference was noted only with respect to the length of the root canal filling ( $p = 0.023$ ,  $\chi^2$ -test).

Comparing all the variables with respect to the length of the root canal filling, statistically significant differences were found for the following: the number of previous treatments/retreatments, attempted endodontic retreatment before endodontic surgery, homogeneous filling, spontaneous pain, the presence of intracanal posts (metal individual and composite) and the presence of bone dehiscence (Table 2).

(5.4%), nijedan postupak (2,7 %) i ekstrakcija (1,8 %) bili su rjeđi. Većina uključenih zuba bili su maksilarni sjekutići (66 %). Većina je bila protetički rekonstruirana (62,9 %), a više od pola (53,5 %) imalo je intrakanalnu nadogradnju (tablica 1.).

Punjjenje korijenskog kanala bilo je homogeno i unutar 1 mm od apeksa u 21,6 % slučajeva, a u 78,4 % slučajeva punjenje je bilo nezadovoljavajuće prema kriteriju homogenosti i/ili duljine punjenja. Analizom odnosa homogenosti punjenja (homogeno ili nehomogeno) i svih ostalih varijabli, statistički značajna povezanost ustanovljena je jedino za duljinu punjenja ( $p = 0,023$ ,  $\chi^2$ -test).

Uspoređujući sve varijable s duljinom punjenja korijenskog kanala, statistički značajne razlike ustanovljene su za sljedeće varijable: broj prethodnih liječenja/revizija, pokušaj revizije prije endodontske kirurgije, homogenost punjenja, spontana bol, prisutnost intrakanalne nadogradnje (metalne individualne i kompozitne) i dehiscencija kosti (tablica 2.).

**Table 2** The variables that were significantly related to the length of the root canal filling were determined using  $\chi^2$ -test.  
**Tablica 2.** Varijable značajno povezane s duljinom punjenja korijenskog kanala odredene s pomoću  $\chi^2$ -testa

## Discussion

Endodontic surgery was the preferred procedure in 90% of the referred cases. The main hypothesis of the research was thus affirmed. Non-surgical retreatment was attempted in a

## Rasprava

Endodontsko-kirurški zahvat bio je preferiran u 90 % upućenih slučajeva. Zato je potvrđena glavna hipoteza istraživanja. Nekirurška revizija pokušala se učiniti u razmjerno

relatively low percentage of the referred cases (20.6 %), even though root canal fillings were unsatisfactory in most of them.

Residual infection due to inadequate cleaning and disinfection of the root canal space, or secondary infection due to inadequate obturation/sealing may lead to endodontic treatment failure (20). Intra-radicular microflora is polymicrobial, predominantly anaerobic and resembles to that of an untreated necrotic pulp (21). Therefore, in cases where an orthograde approach is possible, endodontic retreatment should be the treatment of choice. It was reported that the healing of periapical lesions after endodontic retreatment occurs in 74-98% of the cases, while the success rate of endodontic surgery, without previous retreatment, was significantly lower (13, 12, 20). Furthermore, research by Torabinejad *et al.* (22) showed that the success of orthograde treatment lasted longer. Previous studies also report significant percentage of cases in which endodontic surgery was conducted, although according to the scientifically grounded criteria, orthograde retreatment should have been the treatment of choice (18, 23). It was concluded in previous studies that general dental practitioners do not appreciate endodontic retreatment as a treatment option, and the inclusion of a specialist of endodontics in the decision-making process on endodontic surgery was suggested (18, 23, 24). Moreover, in almost 3% of the cases endodontics was not performed and in more than 65% of cases endodontic treatment was conducted only once, less than 3% performed by a specialist of endodontics.

Oral surgery specialization bias in decision making was the subject of some previous studies where the referred patients were reassessed and based on audit criteria the authors reported that the endodontic surgery had not been indicated in considerable number of the patients (18, 23, 25). Abramowitz *et al.* (18) came to conclusion that the percentage of "unnecessary" resections" was 55%. Anyway, it is important to point out that the concept of endodontic surgery implies root-end resection with retrograde cavity filling, and that omitting the retrograde filling should negatively affect the outcome of the surgery. Since the purpose of our research was not to define the percentage of "unnecessary" endodontic surgeries, we are unable to give such assessments for our sample. However, we can conclude that certain number of cases could have been treated more conservatively, by an orthograde retreatment approach, especially considering intraradicular infection remaining after endodontic surgery in cases that had not been orthogradely retreated before. Nevertheless, it would be interesting to follow up the cases referred to oral surgery that had been treated surgically and those that had been forwarded to an endodontics specialist for orthograde retreatment. At this point there is no systematic follow up of patients referred to Oral surgery and Endodontics at the School of Dental Medicine, and majority of patients are followed by their primary dentist. It was therefore at this point difficult to obtain the data necessary for the assessment of the success rates of surgical and conservative treatments, and assess the percentage of unnecessary surgeries. We can however notice that in the von Arx *et al.* (25) study, the percentage of teeth in which an oral surgery specialist decided for root-end resection was significantly lower (59.1%)

malom postotku (20,6 %), premda punjenja korijenskih kana u glavnom nisu zadovoljavala.

Rezidualna infekcija zbog neadekvatnog čišćenja i dezinfekcije korijenskog kanala ili sekundarne infekcije zbog neadekvatne opturacije mogu rezultirati neuspjehom endodontskog liječenja (20). Intraradikularna mikroflora je polimikrobnja i prevladavajuće anaerobna te je nalik na onu u netretiranoj nekrotičnoj pulpi (21). Zato bi u slučaju kada je moguće ortogradni pristup, revizija endodontskog liječenja trebala biti postupak izbora. Podaci iz literature pokazuju da se cijeljenje periapikalnih lezija nakon revizije liječenja događa u 74 do 98 % slučajeva, a značajno je manji postotak uspješnosti endodontske kirurgije, bez prethodne revizije (13, 12, 20). Nadalje, istraživanje Torabinejada i suradnika (22) pokazalo je da je uspjeh nakon ortogradne revizije dugotrajniji. Ranija istraživanja također govore o značajnom postotku slučajeva za koje je provedena endodontska kirurgija, a prema znanstveno utemeljenim kriterijima postupak izbora trebala je biti ortogradna revizija (18, 23). U ranijim istraživanjima zaključeno je da primarni stomatolozi ne cijene endodontsku reviziju kao terapijsku mogućnost te je predloženo uključivanje specijalista endodoncije u proces odlučivanja o provedbi endodontsko-kirurškog zahvata (18, 23, 24). Nadalje, u gotovo 3 % slučajeva endodoncija nije nikad provedena, u 65 % slučajeva endodontski je tretman obavljen samo jedanput, a u manje od 3 % liječio ju je specijalist endodoncije.

Utjecaj specijalizacije iz oralne kirurgije na odluku o postupku, bio je tema nekoliko ranijih istraživanja u kojima se upućene pacijente ponovno procjenjivalo prema revidiranim kriterijima pa su autori naveli da endodontsko-kirurški zahvat nije bio indiciran u velikom broju slučajeva (18, 23, 25). Abramovitz i suradnici (18) zaključili su da je postotak *nepotrebnih* resekcija 55 %. Ipak, važno je istaknuti da koncept oralne kirurgije obuhvaća resekciju vrška korijena s retrogradnim punjenjem, a izostavljanje retrogradnog punjenja negativno utječe na ishod operativnog zahvata. Budući da svrha ovog istraživanja nije bila utvrditi postotak *nepotrebnih* kirurških zahvata, nismo u stanju dati takvu procjenu za naš uzorak. No možemo zaključiti da je određeni broj slučajeva mogao biti tretiran konzervativnije, posebno ako se uzme u obzir intraradikularna infekcija koja ostaje u kanalu nakon endodontsko-kirurškoga zahvata u slučaju da prije nije učinjena revizija. Ipak, bilo bi zanimljivo pratiti slučajeve upućene na oralnu kirurgiju koji su kirurški tretirani i one proslijedene specijalistu endodoncije zbog ortogradne revizije liječenja. Trenutačno ne postoji sustavno praćenje pacijenata upućenih i obradenih u Zavodu za oralnu kirurgiju i Zavodu za endodonciju te je većinu pratio njihov primarni stomatolog. Zato je zasad teško doći do podataka na temelju kojih bi se odredio postotak uspješnosti kirurškog i konzervativnog tretmana te postotak nepotrebnih operacija. Možemo ipak istaknuti da je u istraživanju von Arxa i suradnika (25) postotak zuba za koje se specijalist oralne kirurgije odlučio za resekciju bio značajno niži (59,1 %), negoli u našem istraživanju (90 %). To može biti zbog toga što se naš uzorak većinom sastojao od pacijenata s već dogovorenim operacijama.

Radiološki procijenjena kvaliteta punjenja korijenskih

than in our study (90%). The reason for this difference is that our sample consisted mostly of patients with an already scheduled surgery.

Radiographically estimated quality of root canal fillings done by general practitioners in Sweden was satisfactory in only 31% of the cases and after a course in machine endodontics, the quality was significantly improved and was satisfactory in 51% of the cases (26). Similarly, in our research, 45% of fillings were estimated as homogeneous (Table 1). The Swedish authors reported that the homogeneity and filling length had no influence on the size of the periapical lesion, also similar to our results.

When it comes to symptoms before operation, we found significant connection between the filling length and spontaneous pain ( $p < 0.05$ ). It is interesting that spontaneous pain and alveolar bone loss (presence of dehiscence) were more commonly recorded when the filling was the satisfactory in length ( $p < 0.05$ ), i.e. within 1 mm from the apex.

In our research 21.6% of the cases with adequate fillings had symptoms or did not show signs of healing. The reason for that can be intraradicular infection with microorganisms resistant to intracanal medicaments and irrigants, which lead to failure after *lege artis* endodontic treatment (7, 27). Additionally, the elimination of infection from the apical part of the canal and consequent failure might be caused by procedural mistakes done during primary endodontic treatment, that are not necessarily radiographically detectable, e.g. transposition and transportation of apex (20, 28). The decision about the treatment should therefore not be based solely on the radiographic finding (17). In our research, the connection between the treatment decision and radiographically estimated quality of filling was not significant ( $p < 0.05$ ). Although the diagnostic value of panoramic radiographs is inferior (29), the panoramic radiographs were in our study included in the analysis. The reason for including them is their low number (only 2), and their reported sufficient diagnostic value in diagnosing apical periodontitis (30).

In addition to intraradicular infection, the cause of failure of endodontic treatment can be an extraradicular infection in the form of periradicular actinomycosis, foreign body reaction or true cyst (7, 9). In these cases, healing and/or withdrawal of symptoms after endodontic retreatment cannot be expected, and surgical approach is indicated: root-end resection and the removal of foreign body or excochleation of the radicular cyst (9). However, these treatment failure causes are relatively rare, and intraradicular microbial infection in the apical part of root canal remains the most common cause of endodontic treatment failure (7, 10).

Almost 63% of the cases in our study were prosthetically reconstructed and more than 30% had intracanal post. This made orthograde approach to root canal difficult, and presumably this was the main reason these patients were referred to endodontic surgery, although, according to the criteria of radiographic appearance of the fillings, orthograde retreatment should have been the first choice. In the context of the rationalization we realize that endodontic surgery seems like a favourable choice in such cases, because prosthetic work is preserved. Within our sample, 50% of the referred crowned

kanala koje su liječili primarni stomatolozi u Švedskoj bila je zadovoljavajuća u samo 31 % slučajeva, a nakon tečaja o strojnoj endodonciji kvaliteta punjenja značajno se popravila te je zadovoljavala u 51 % slučajeva (26). Slično tomu, u našem je istraživanju 45 % punjenja bilo procijenjeno kao homogeno (tablica 1.). Švedski su autori također naveli da homogenost i duljina punjenja nisu bile u korelaciji s veličinom periapikalne lezije, što je bio slučaj i u našem istraživanju. Kad su u pitanju simptomi prije operacije, našli smo značajnu povezanost između duljine punjenja i spontane boli ( $p < 0,05$ ). Zanimljivo je da su spontana bol i gubitak alveolarne kosti (dehiscencija) bili češći kada je punjenje bilo zadovoljavajuće duljine ( $p < 0,05$ ), i.e. unutar 1 mm od apeksa.

U našem je istraživanju 21,6 % slučajeva s adekvatnim punjenjem imalo simptome ili nije pokazivalo znakove cijeljenja. Uzrok može biti intraradikularna infekcija mikroorganizmima rezistentnih na intrakanalne lijekove i irrigante, što obično završava neuspjehom nakon endodontskog postupka *lege artis* (7, 27). Nadalje, zaostala infekcija u apikalnom dijelu kanala i posljedični neuspjeh, mogu biti uzrokovani proceduralnim pogreškama tijekom primarnog endodontskog liječenja koje nisu nužno detektibilne na radiogramu, to su, na primjer, transpozicija i transportacija apeksa (20, 28). Odluka o postupku zato se ne bi trebala temeljiti samo na radiološkom nalazu (17). U našem istraživanju nije bilo značajne povezanosti između odluke o postupku i radiološki procijenjene kvalitete punjenja ( $p < 0,05$ ). Premda je dijagnostička vrijednost ortopantomografske slabije (29), oni su u našoj studiji uključeni u analizu. Razlog za to bio je njihov mali broj (samo 2) i njihova, prema literaturi, dosta dijagnostička vrijednost u dijagnozi apikalnog parodontitisa (30).

Uz intraradikularnu infekciju, uzrok za neuspjeh endodontske terapije može biti ekstraradikularna infekcija u obliku periradicularne aktinomikoze, reakcije stranog tijela i pravih cista (7, 9). U tim slučajevima cijeljenje i/ili povlačenje simptoma nakon revizije liječenja ne može se očekivati te je indiciran kirurški pristup – resekcija vrška korijena i uklanjanje stranog tijela ili ekskohleacija radikularne ciste (9). No ti uzroci neuspjeha razmjerno su rijetki, pa intraradikularna mikrobnna infekcija u apikalnom dijelu ostaje najčešći uzrok za neuspjeh endodontske terapije (7, 10).

Čak je 63 % slučajeva u našoj studiji bilo protetički rekonstruirano, a više od 30 % imalo je intrakanalnu nadogradnju. To je otežalo ortogradni pristup liječenju korijenskog kanala te je to vjerojatno bio glavni razlog za upućivanje pacijenata na endodontsku kirurgiju, premda je prema kriterijima radiološkog izgleda punjenja, ortogradna revizija trebala biti prvi izbor. U kontekstu racionalizacije, izbor endodontske kirurgije čini se dobrim jer je sačuvan protetički rad. U našem uzorku 50 % okrunjenih zuba bili su nosači mosta. Ipak, ortogradna revizija prije kirurškog postupka značajno povećava izglede za uspjeh endodontskog kirurškog zahvata (20). Čak ni intrakanalne nadogradnje ne bi trebale biti izravan kriterij za isključivanje revizije kao terapijskog postupka (20, 23). Uz to, velik broj nadogradnji u našem istraživanju bio je kraći od 5 mm, što je također jedan od kriterija koji Zub čini potencijalnim kandidatom za ortogradnu reviziju (23).

teeth were bridge carriers. Nevertheless, orthograde retreatment of the root canal filling before surgical procedure significantly increases the chances of success of endodontic surgery (20). Even the presence of intracanal posts should not mean immediate exclusion of retreatment as a therapeutic procedure of choice (20,23). Additionally, great number of posts in our sample was shorter than 5 mm which is also one of the criteria that makes a tooth a potential candidate for orthograde retreatment (23).

## Conclusions

Endodontic surgery was a procedure of choice for most patients referred by a general practitioner to an oral surgery specialist. Considering that the percentage of radiographically assessed teeth with unsatisfactory root canal fillings was high, and the percentage of teeth in which orthograde retreatment was attempted prior to the referral to oral surgery specialist was low, we can conclude that the awareness about the possibilities of successful treatment by non-surgical approach is insufficient.

### Sažetak

**Svrha:** Svrha istraživanja bila je radiološki procijeniti kvalitetu punjenja korijenskih kanala pacijentima upućenima na endodontski kirurški zahvat te korelirati nalaz s odlukom o terapiji. Također su se željeli analizirati klinički simptomi i veličina periapikalne lezije na radiogramu i povezati ih s odlukom o terapijskom postupku, uključujući nekiruršku reviziju liječenja, endodontsku kirurgiju i ekstrakciju. **Materijali i postupci:** Sastavljen je upitnik za prikupljanje podataka. U istraživanju je sudjelovalo 86 pacijenata (sa 109 zuba) upućenih na endodontski kirurški zahvat. Kvaliteta punjenja korijenskih kanala procijenjena je prema homogenosti i duljini punjenja na digitalnim radiogramima. Podatci su analizirani  $\chi^2$ -testom i t-testom. **Rezultati:** Od zuba kojima je bio potreban endodontski kirurški zahvat, 97,2 % prije je liječio primarni liječnik dentalne medicine, endodontska revizija punjenja primjenjena je u 20,6 % slučajeva, a punjenje korijenskog kanala bilo je homogeno i unutar 1mm od apeksa sa 21,6 % slučajeva. Endodontska kirurgija, revizija, ekstrakcija ili nijedan postupak, odabrani su redom u 90,1 %, 5,4 %, 1,8 % i 2,7 % slučajeva. **Zaključak:** Nizak postotak adekvatnih punjenja korijenskog kanala i visok postotak kad je riječ o odlukama za endodontski kirurški postupak, sugeraju da postoji potreba za povećanjem svijesti o mogućoj nekirurškoj reviziji endodontskog liječenja.

## Zaključak

Endodontska kirurgija bila je postupak izbora za većinu pacijenata koje je primarni stomatolog uputio oralnom kirurgu. Uzimajući u obzir da je postotak zuba s radiološkim utvrđenim neadekvatnim punjenjem bio visok, a postotak onih na kojima se pokušala učiniti revizija prije upućivanja na kirurgiju mali, zaključujemo da znanje o mogućnostima uspješnog nekirurškog liječenja nije dovoljno.

## Zahvala

Rezultati ovog istraživanja prezentirani su u Zagrebu 2017. u obliku postera na međunarodnom kongresu *Sinergija znanosti i kliničkoga rada*.

Istraživanje je obavljeno u sklopu potpore Sveučilišta u Zagrebu *Komparativna evaluacija rotirajuće i recipročne strojne endodontske tehnike – klinička studija* (voditeljica prof. dr. sc. Goranka Prpić Mehicić - 2017.).

## Sukob interesa

Autori nisu bili u sukobu interesa.
