### Abstract

The versatility of Ca<sup>2+</sup> signals derives from their spatio-temporal organization<sup>1,2</sup>. For Ca<sup>2+</sup> signals initiated by inositol trisphosphate (IP<sub>3</sub>) this requires local interactions between IP<sub>3</sub> receptors (IP<sub>3</sub>R)<sup>3,4</sup> mediated by their rapid stimulation and slower inhibition<sup>4</sup> by cytosolic Ca<sup>2+</sup>. This allows hierarchical recruitment of Ca<sup>2+</sup> release events as the IP<sub>3</sub> concentration increases<sup>5</sup>. Single IP<sub>3</sub>R respond first, then clustered IP<sub>3</sub>R open together giving a local Ca<sup>2+</sup> puff, and as puffs become more frequent they ignite regenerative Ca<sup>2+</sup> waves<sup>1,5-9</sup>. We demonstrate, using nuclear patch-clamp recording<sup>10</sup>, that IP<sub>3</sub>R are initially randomly distributed with an estimated separation of ~1 μm. Low concentrations of IP<sub>3</sub> cause IP<sub>3</sub>R to aggregate rapidly and reversibly into small clusters of ~4 closely associated IP<sub>3</sub>R. At resting cytosolic [Ca<sup>2+</sup>], clustered IP<sub>3</sub>R open independently, but with lower open probability ( $P_o$ ), shorter open time, and lesser IP<sub>3</sub> sensitivity than lone IP<sub>3</sub>R. Increasing cytosolic [Ca<sup>2+</sup>] reverses the inhibition caused by clustering, IP<sub>3</sub>R gating becomes coupled, and the duration of multiple openings is prolonged. Clustering both exposes IP<sub>3</sub>R to local Ca<sup>2+</sup> rises and increases the effects of Ca<sup>2+</sup>. Dynamic regulation of clustering by IP<sub>3</sub> tunes IP<sub>3</sub>R sensitivity to IP<sub>3</sub> and Ca<sup>2+</sup>, facilitating hierarchical recruitment of the elementary events that underlie all IP<sub>3</sub>-evoked Ca<sup>2+</sup> signals<sup>3,5</sup>.

IP<sub>3</sub>-activated currents recorded from patches excised from the outer nuclear envelope of DT40 cells<sup>10</sup> expressing rat IP<sub>3</sub>R3 are entirely due to IP<sub>3</sub>R3 (Fig. 1). With 10 μM IP<sub>3</sub> in the pipette solution (PS) the single channel open probability ( $P_o$ ) was  $0.44 \pm 0.05$  ( $n = 6$ ) and the mean open time ( $\tau_o$ ) was  $11.9 \pm 1.6$  ms. The distribution of closed times ( $\tau_c$ ) had two components (Fig. 1d). Recordings in the on-nucleus configuration confirmed these results (not shown). The results are consistent with the gating scheme shown in Figure 1d (see Supplementary Methods).

The number of channels within a patch ( $1.34 \pm 0.13$ ,  $n = 109$ ) can be estimated reliably from the largest multiple of simultaneous openings to the unitary current level (Fig. 1e, Methods). The distribution of IP<sub>3</sub>R in a patch is random: it is not significantly different from a Poisson distribution ( $\chi^2$ ,  $p > 0.05$ ; Fig. 1f, Supplementary Table 1). Others suggested that IP<sub>3</sub>R are clustered in the nuclear envelope<sup>11,12</sup>, but it seems likely that in making repeated recordings from the same nucleus they stimulated nuclei with IP<sub>3</sub> before recording and thereby caused IP<sub>3</sub>R clustering (see below).

Channel activity ( $P_o$ , Fig. 2a-c), but not the number of active IP<sub>3</sub>R (Fig. 2d), increased with IP<sub>3</sub> concentration ( $EC_{50} = 1.38 \pm 0.03$  μM for patches with one IP<sub>3</sub>R). There was more than

one IP<sub>3</sub>R in 57% of active patches, and each opened to the same  $\gamma$  (Fig. 1e, 2a), but  $NP_0$  (the overall channel activity) was less than expected from the summed behaviour of lone IP<sub>3</sub>R (Fig. 2e). For multi-IP<sub>3</sub>R patches, the sensitivity to IP<sub>3</sub> of  $NP_0$  was also significantly reduced ( $EC_{50} = 2.47 \pm 0.25 \mu\text{M}$  for patches with 3 IP<sub>3</sub>R, Fig. 2c, Supplementary Table 2). Do IP<sub>3</sub>R behave independently in such multi-IP<sub>3</sub>R patches or do they interact, like some ryanodine receptors<sup>13,14</sup>? For each of the four states in patches with three IP<sub>3</sub>R (closed and 1, 2 or 3 simultaneously open IP<sub>3</sub>R),  $P_0$  predicted from the binomial distribution matched the observed  $P_0$  (Fig. 2f, Methods). Similar results were obtained for patches with different numbers of IP<sub>3</sub>R and for type 1 IP<sub>3</sub>R (Supplementary Figs 1, 2). At resting cytosolic  $[\text{Ca}^{2+}]$ , therefore, each IP<sub>3</sub>R within a multi-IP<sub>3</sub>R patch behaves identically and opens independently.

How can randomly distributed IP<sub>3</sub>R that open independently behave with such uniformity, and yet so differently from lone IP<sub>3</sub>R, when a patch fortuitously contains several IP<sub>3</sub>R? Recordings from *Xenopus* nuclei also suggest that heterogenous behaviour of lone IP<sub>3</sub>R becomes more uniform when patches contain several IP<sub>3</sub>R<sup>15</sup>. We suggest that IP<sub>3</sub> causes IP<sub>3</sub>R to cluster<sup>16</sup> and that clustered IP<sub>3</sub>R are less active. To test this hypothesis, nuclei were bathed in IP<sub>3</sub> (10  $\mu\text{M}$ , 2 min) before forming seals for patch-clamp recording. In these paired experiments, the mean number of IP<sub>3</sub>R per patch was unaffected by IP<sub>3</sub>-pre-treatment (Supplementary Table 1), confirming that IP<sub>3</sub> neither inactivated IP<sub>3</sub>R nor affected the area of membrane trapped beneath the patch. But the distributions of IP<sub>3</sub>R were very different before and after IP<sub>3</sub> treatment (Fig. 3a). In naïve nuclei IP<sub>3</sub>R were randomly distributed (Fig. 3b), but their distribution after IP<sub>3</sub>-pre-treatment differed significantly from the Poisson distribution ( $p < 0.05$ ): many patches had no IP<sub>3</sub>R, single IP<sub>3</sub>R were under-represented, and several patches had unusually large numbers of IP<sub>3</sub>R (Fig. 3c). This clustering of IP<sub>3</sub>R fully reversed within 8-10 min of removing IP<sub>3</sub> (Fig. 3a, d).  $P_0$  of lone IP<sub>3</sub>R from naïve nuclei ( $0.44 \pm 0.05$ ,  $n = 6$ ) was indistinguishable from  $P_0$  of the only lone IP<sub>3</sub>R caught within a patch after IP<sub>3</sub> pre-treatment ( $0.41$ ).  $P_0$  for each IP<sub>3</sub>R within a cluster was also indistinguishable for recordings from naïve ( $0.24 \pm 0.01$ ,  $n = 18$ ) and IP<sub>3</sub>-pre-treated nuclei ( $0.25 \pm 0.01$ ,  $n = 18$ ). Furthermore, there was no decrease in  $P_0$  during recordings that outlasted the IP<sub>3</sub> pre-treatment (Supplementary Fig. 3). We conclude that clustering, rather than IP<sub>3</sub> *per se*, decreases  $P_0$ .

The decrease in  $P_0$  as IP<sub>3</sub>R cluster is identical whether clustering is evoked by application of IP<sub>3</sub> to an isolated patch (Fig. 2e, h) or the entire nucleus (Fig. 3e). Both reduce  $P_0$  to ~54% that of lone IP<sub>3</sub>R. The latter condition better replicates the situation *in vivo*, confirming that results with isolated patches (Figs 1, 2) faithfully report the behaviour of IP<sub>3</sub>R roaming freely within the nuclear envelope. The effect of cluster size on  $P_0$  indicates that pairing of IP<sub>3</sub>R is sufficient to cause the maximal decrease in  $P_0$ . Additional IP<sub>3</sub>R can join a cluster, and their activity is attenuated, but IP<sub>3</sub>R within larger clusters are no more inhibited than pairs of IP<sub>3</sub>R (Figs 2g, h, Supplementary Table 2). IP<sub>3</sub>R associate with actin<sup>4</sup> and microtubules<sup>17</sup>, but neither is required for clustering-evoked changes in  $P_0$  (Supplementary Fig. 4).

To examine the effects of clustering on IP<sub>3</sub>R gating, we compared mean open time ( $\tau_0$ , Supplementary Information) of lone IP<sub>3</sub>R with  $\tau_0$  for single channel openings from patches with several ( $N$ ) IP<sub>3</sub>R (blue line in Fig. 3f). These  $\tau_0$  should be similar if lone and grouped IP<sub>3</sub>R behave identically. For multi-IP<sub>3</sub>R patches, we also measured the duration of events in which all IP<sub>3</sub>R were simultaneously open ( $\tau_{0,N}$ , red line in Fig. 3f), and from that calculated  $\tau_0$  for individual, independently gated IP<sub>3</sub>R ( $=N\tau_{0,N}$ ). Both analyses gave the same result:  $\tau_0$  for IP<sub>3</sub>R within a cluster was reduced to 47% of that for lone IP<sub>3</sub>R (Fig. 3f). A similar analysis of closed states confirmed that neither was affected by clustering (Supplementary Fig. 5, Supplementary Table 3). IP<sub>3</sub>-evoked clustering almost doubles the rate of channel closure ( $1/\tau_0$ ) and this is alone sufficient (Supplementary Fig. 6, Supplementary Table 4) to

account for the decreased  $P_o$  of clustered IP<sub>3</sub>R (Fig. 2g). Clustered IP<sub>3</sub>R open for half as long as lone IP<sub>3</sub>R (5.4 vs 11.9 ms), and pairing of IP<sub>3</sub>R is enough to cause the full effect (Fig. 2g). Other regulators of IP<sub>3</sub>R usually influence  $\tau_c$  and so rates of channel opening<sup>4</sup>. The difference is important because  $\tau_o$  will affect the time course of the initial Ca<sup>2+</sup> release within elementary events<sup>7</sup> and thereby Ca<sup>2+</sup>-mediated interplay between clustered IP<sub>3</sub>R. This is confirmed by simulations of intracellular Ca<sup>2+</sup> spikes, where the ~50% decrease in  $\tau_o$  of clustered IP<sub>3</sub>R causes the frequency of Ca<sup>2+</sup> spiking to decrease by 4-fold (Supplementary Fig. 7).

Within a patch, cluster size is limited to the number of IP<sub>3</sub>R fortuitously caught beneath the patch-pipette, but for nuclei pre-treated with bath-applied IP<sub>3</sub> the clusters are larger (Fig. 3c). This demonstrates that a maximal concentration of IP<sub>3</sub> causes >93% of IP<sub>3</sub>R to cluster (85/91 IP<sub>3</sub>R from 88 nuclei pre-treated with IP<sub>3</sub>) and the average cluster contains  $4.25 \pm 0.38$  IP<sub>3</sub>R (Methods). Inhibition of IP<sub>3</sub>R within a cluster is not caused by feedback inhibition<sup>4</sup> from Ca<sup>2+</sup> passing through neighbouring IP<sub>3</sub>R. Both BS and PS have the same [Ca<sup>2+</sup>] and are buffered with BAPTA, the inhibition occurs at positive (Fig. 2) and negative holding potentials (Supplementary Discussion), and clustered IP<sub>3</sub>R open independently (Fig. 2f). Because permeating ions cannot regulate neighbouring IP<sub>3</sub>R under our recording conditions, inhibition must be mediated by contacts between IP<sub>3</sub>R. From this, we estimate that the average separation of IP<sub>3</sub>R falls from ~1  $\mu\text{m}$  to ~20 nm after clustering, and that clusters are ~2  $\mu\text{m}$  apart (Supplementary Discussion). These spacings concur with confocal measurements suggesting that a Ca<sup>2+</sup> puff originates from a cluster ~50 nm wide and that clusters are ~3  $\mu\text{m}$  apart<sup>18</sup>. When expressed at high densities, IP<sub>3</sub>R<sup>19</sup> and ryanodine receptors<sup>20</sup> form arrays with each tetrameric receptor contacting four others. We speculate that IP<sub>3</sub>-evoked clusters (of  $4.25 \pm 0.38$  IP<sub>3</sub>R) exploit similar contacts and so, with single IP<sub>3</sub>R, form the fundamental units of Ca<sup>2+</sup> signalling (Fig. 3g).

IP<sub>3</sub>-evoked clustering is complete within seconds of stimulation with a maximal concentration of IP<sub>3</sub> (Supplementary Fig. 3). To resolve the time course, we used photolysis of caged IP<sub>3</sub> rapidly to increase the IP<sub>3</sub> concentration bathing IP<sub>3</sub>R trapped beneath the patch-pipette. IP<sub>3</sub>R were initially quiescent and then rapidly activated when IP<sub>3</sub> was photo-released (Fig. 3h). Irrespective of the number of IP<sub>3</sub>R caught within a patch,  $\tau_o$  was initially similar for all IP<sub>3</sub>R (~10 ms). It then remained stable for many minutes for lone IP<sub>3</sub>R ( $11.4 \pm 0.5$  ms), but  $\tau_o$  fell within 2.5 s to  $5.8 \pm 0.3$  ms for patches containing more than one IP<sub>3</sub>R (Fig. 3i, Supplementary Fig. 8). Using  $\tau_o$  to report IP<sub>3</sub>R clustering suggests that clustering is complete within 2.5 s of IP<sub>3</sub> addition. A similar analysis of  $P_o$  suggests a half-time for clustering of ~1.5-2 s (Fig. 3i). Our evidence that clustering does not require the cytoskeleton and measurements of IP<sub>3</sub>R<sup>3</sup> mobility<sup>21,22</sup> suggest that diffusion alone may be sufficient to allow IP<sub>3</sub>R<sup>3</sup> clustering within a few seconds (Supplementary Discussion).

We can define the IP<sub>3</sub> sensitivity of clustering by measuring the extent to which  $P_o$  of each IP<sub>3</sub>R within a multi-IP<sub>3</sub>R patch ( $P_o = NP_o/N$ , Supplementary Abbreviations) falls below  $P_o$  of an identically stimulated lone IP<sub>3</sub>R ( $P_{\text{one}}$ ). This demonstrates that IP<sub>3</sub>R clustering ( $EC_{50} < 300$  nM) is ~10-times more sensitive to IP<sub>3</sub> than channel opening ( $EC_{50} = 2.02$   $\mu\text{M}$ , Fig. 3e). Steady-state exposure to low IP<sub>3</sub> concentrations that evoke Ca<sup>2+</sup> puffs<sup>5,7</sup> would, by assembling IP<sub>3</sub>R clusters, allow both generation of puffs and loss of Ca<sup>2+</sup> blips<sup>23</sup>.

Clustering moves IP<sub>3</sub>R (~1  $\mu\text{m}$  apart) from being insulated from their neighbours by Ca<sup>2+</sup>-buffering to domains (~20 nm apart) where they will instantly experience high local [Ca<sup>2+</sup>] whenever a neighbour opens<sup>24</sup> (Supplementary Fig. 7). Hitherto (Figs 1-3), we prevented such interactions by using K<sup>+</sup> as charge-carrier and recording at a free [Ca<sup>2+</sup>] (200 nM) that mimics a resting cell. Subsequent experiments include 1  $\mu\text{M}$  free [Ca<sup>2+</sup>] with IP<sub>3</sub> in PS to simulate the [Ca<sup>2+</sup>] near open IP<sub>3</sub>R. For simplicity we use K<sup>+</sup> as charge-carrier. With 1  $\mu\text{M}$

[Ca<sup>2+</sup>] in PS, IP<sub>3</sub>R activity was increased:  $P_o$  for lone IP<sub>3</sub>R almost doubled, as  $\tau_c$  decreased (Fig. 4a). Neither the number of IP<sub>3</sub>R/patch ( $1.12 \pm 0.24$ ) nor their random distribution (Fig. 4b) was affected by Ca<sup>2+</sup>, but the interplay between IP<sub>3</sub>R was altered. Whereas clustering reduced the overall activity of IP<sub>3</sub>R ( $NP_o$ ) at resting [Ca<sup>2+</sup>] (Fig. 2e), the inhibition was reversed by increased [Ca<sup>2+</sup>], such that the collective activity of a pair of IP<sub>3</sub>R ( $NP_o$ ) was the same as that predicted from the summed activity of two lone IP<sub>3</sub>R (Fig. 4c). This did not result from disaggregation of clusters because at increased [Ca<sup>2+</sup>], IP<sub>3</sub>R no longer opened independently. In patches with two IP<sub>3</sub>R (open-channel noise prevented analysis of larger clusters), open probabilities did not fit the binomial distribution (Fig. 4e): double open and closed events were over-represented (Supplementary Fig. 9). Furthermore, there were many examples of IP<sub>3</sub>R opening and closing directly to and from states with both IP<sub>3</sub>R open (Fig. 4d). For paired IP<sub>3</sub>R, the double openings were prolonged by 50% (Fig. 4f), but 47% less frequent than expected (Fig. 4g). The overall increase in  $P_o$  for double openings was therefore small (12%) and counteracted by a 39% decrease in the probability of only one IP<sub>3</sub>R being open and a 116% increase in the probability of both being closed (Fig. 4e). Clustered IP<sub>3</sub>R exposed to increased [Ca<sup>2+</sup>] do not therefore behave independently. Their gating is coupled<sup>13,14</sup>: they are more likely to open and close together, and their simultaneous openings are prolonged (Supplementary Fig. 9). Coupled gating is not caused by local increases in cytosolic [Ca<sup>2+</sup>], and must instead result from physical coupling of IP<sub>3</sub>R. Under physiological conditions, clustered IP<sub>3</sub>R are more likely to experience increased [Ca<sup>2+</sup>] (because their neighbours may release it), and they are also tuned to respond most to it. By suppressing IP<sub>3</sub>R activity at resting [Ca<sup>2+</sup>], clustering increases the impact of a subsequent local increase in [Ca<sup>2+</sup>] (Supplementary Fig. 7). Within a cluster, increased Ca<sup>2+</sup> increases  $P_o$  (as it does for lone IP<sub>3</sub>R), but it also reverses the inhibition evoked by clustering and it causes coupled gating. These interactions exaggerate the effect of Ca<sup>2+</sup> within a cluster (Fig. 4h). We conclude that IP<sub>3</sub> dynamically regulates the assembly and behaviour of Ca<sup>2+</sup> puff sites. IP<sub>3</sub> rapidly drives IP<sub>3</sub>R into small clusters, wherein their IP<sub>3</sub> and Ca<sup>2+</sup> sensitivities are re-tuned to exaggerate Ca<sup>2+</sup>-mediated recruitment of IP<sub>3</sub>R and allow hierarchical recruitment of Ca<sup>2+</sup> release events (Fig. 4h, Supplementary Fig. 7)<sup>5,7</sup>.

## METHODS SUMMARY

Nuclei from DT40-IP<sub>3</sub>R3 cells<sup>25</sup> were used for patch-clamp recording from excised patches<sup>10</sup>.

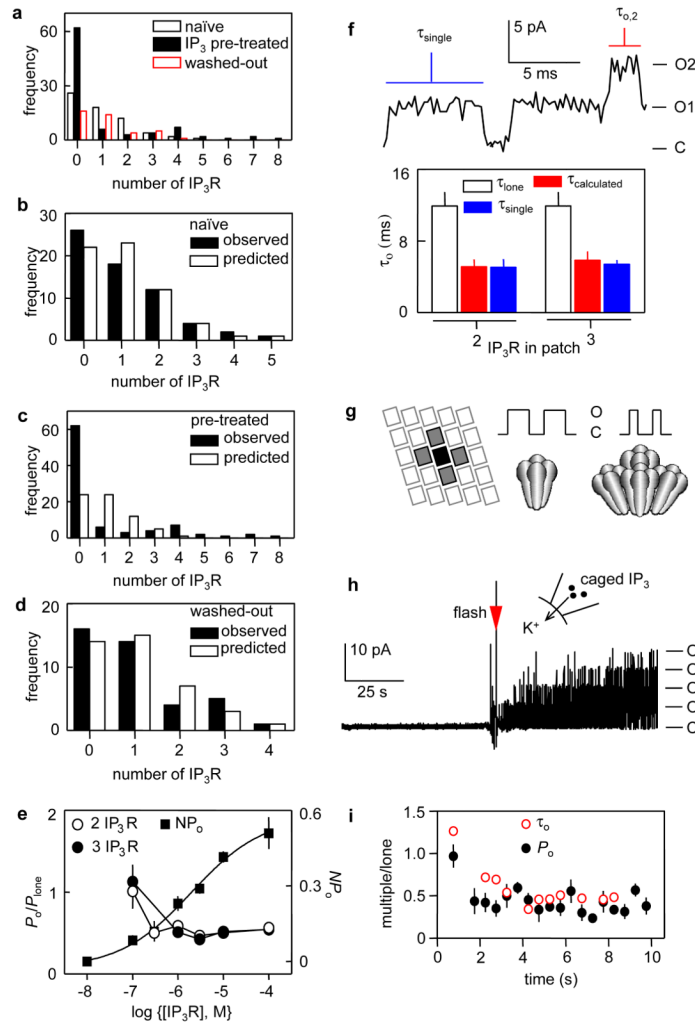

**Figure 1. IP<sub>3</sub>R are randomly distributed**

**a**, IP<sub>3</sub>-evoked Ca<sup>2+</sup> release from permeabilized DT40-IP<sub>3</sub>R3 (EC<sub>50</sub> = 281 ± 46 nM) and DT40-KO cells (means ± SEM, n = 3). Immunoblot with IP<sub>3</sub>R3-specific antiserum (10 μg membrane protein/lane, 220-kDa marker shown). **b**, Currents recorded from excised patches with 10 μM IP<sub>3</sub> in PS. No currents were detected without IP<sub>3</sub> (n = 20), with heparin (100 μg/ml) and IP<sub>3</sub> (n = 15), or with IP<sub>3</sub> in DT40-KO cells (n > 30). C denotes closed state. **c**, *i*-*V* relationship for IP<sub>3</sub>-evoked current (γ<sub>K</sub> = 121 ± 2.8 pS, n = 7). **d**, Dwell time distribution of single IP<sub>3</sub>R3 stimulated with 10 μM IP<sub>3</sub>. Open time distribution of this typical recording is fitted with a single probability density function (pdf) with τ<sub>o</sub> = 10.4 ms (mean = 11.9 ± 1.6 ms, n = 6). The pdf for the τ<sub>c</sub> distribution has two components (1.07 ms, 88% and 109 ms, 12%). Dwell time distributions are consistent with the gating scheme (Supplementary Methods, Supplementary Figs 5, 6). **e**, Typical all-points current amplitude histogram of an excised patch containing 3 IP<sub>3</sub>R stimulated with 10 μM IP<sub>3</sub>; C and O denote closed and open states. **f**, Observed and predicted numbers of IP<sub>3</sub>R/patch from 109 patches (mean = 1.34) stimulated with 10-100 μM IP<sub>3</sub>.

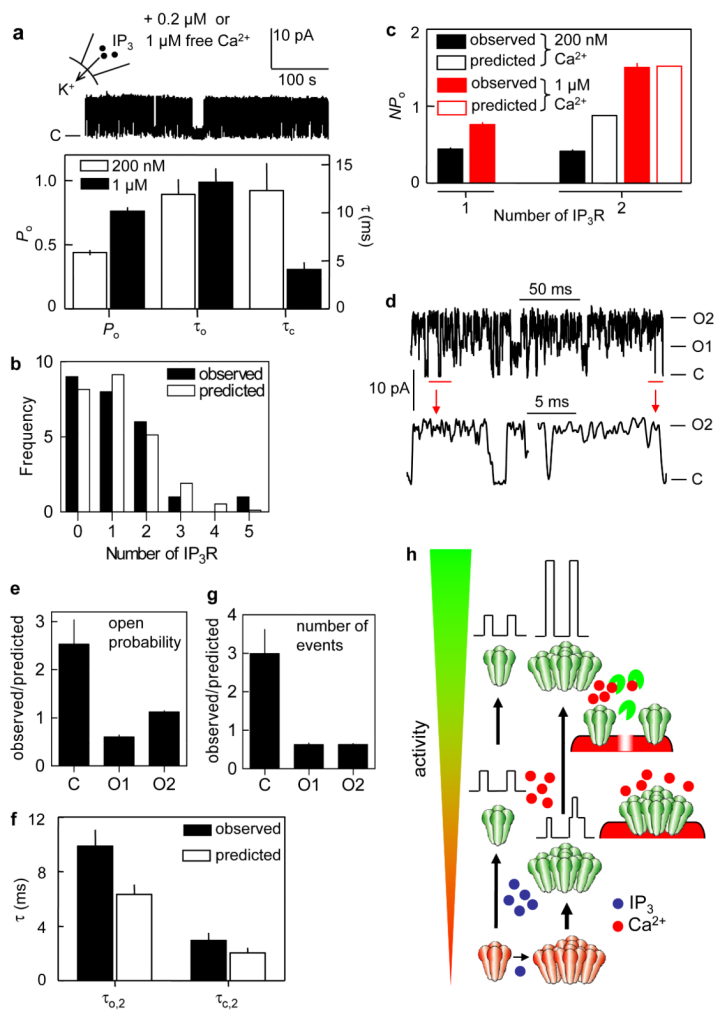

**Figure 2. Lone IP<sub>3</sub>R are more active than clustered IP<sub>3</sub>R at resting cytosolic Ca<sup>2+</sup>**  
**a**, Typical records from patches (2 IP<sub>3</sub>R/patch) stimulated with IP<sub>3</sub> (μM). **b**, **c**, Effect of IP<sub>3</sub> on  $P_o$  of patches containing a single IP<sub>3</sub>R (**b**) or on  $NP_o$  of patches with 3 IP<sub>3</sub>R (**c**) ( $n = 4$ ). **d**, Numbers of IP<sub>3</sub>R detected in each patch for each IP<sub>3</sub> concentration ( $n = 9-25$ ). **e**, Predicted (ie  $NP_{one}$ ) and observed  $NP_o$  for patches containing 1-5 IP<sub>3</sub>R ( $n = 3$ ;  $n = 2$  for 5-IP<sub>3</sub>R patch). **f**, For patches with 3 IP<sub>3</sub>R, observed/predicted values are shown for the indicated numbers of simultaneous openings (Supplementary equation 4). **g**,  $P_o$  as a function of the number of IP<sub>3</sub>R within a patch after stimulation with 10 μM IP<sub>3</sub> (Supplementary equation 5). **h**, Effect of IP<sub>3</sub> on  $P_o$  for lone IP<sub>3</sub>R and IP<sub>3</sub>R within multi-IP<sub>3</sub>R patches ( $n = 4$ ).

### Figure 3. Reversible clustering of IP<sub>3</sub>R by IP<sub>3</sub>

**a**, Numbers of IP<sub>3</sub>R detected in patches from naive nuclei ( $n = 63$ ), after pre-treatment with bath-applied IP<sub>3</sub> ( $10 \mu\text{M}$ ,  $\sim 2$  min;  $n = 88$ ), or the latter after recovery for 8–10 min without IP<sub>3</sub> ( $n = 40$ ). **b–d**, Observed and predicted numbers of IP<sub>3</sub>R/patch. **e**, Effects of IP<sub>3</sub> on IP<sub>3</sub>R clustering and gating. Clustering is reported by  $P_0/P_{\text{one}}$  for patches with 2 or 3 IP<sub>3</sub>R, and gating by  $NP_0$  for patches with 2 IP<sub>3</sub>R ( $EC_{50} = 2.02 \pm 0.20 \mu\text{M}$ ). **f**,  $\tau_0$  for patches with 2 or 3 IP<sub>3</sub>R measured from the duration of single channel openings (blue line,  $\tau_{\text{single}}$ ) or calculated from the duration of openings to the  $N^{\text{th}}$  level (red line,  $\tau_{\text{calculated}} = N \cdot \tau_{0,N}$ ). These are compared with  $\tau_0$  for lone IP<sub>3</sub>R ( $\tau_{\text{lone}}$ ). Typical trace is from a patch with 2 IP<sub>3</sub>R. **g**, IP<sub>3</sub> drives IP<sub>3</sub>R into small clusters consistent with arrays (grey) formed by IP<sub>3</sub>R at high density<sup>19</sup>. Within a cluster, each IP<sub>3</sub>R opens independently, but closes more rapidly than a lone IP<sub>3</sub>R. **h**, Typical recording from a patch containing 4 IP<sub>3</sub>R with IP<sub>3</sub> released from caged IP<sub>3</sub> in PS by flash photolysis (electrical noise caused by the flash is shown). **i**, From records similar to **h** (Supplementary Fig. 8),  $P_0$  (from  $NP_0/N$ ) and  $\tau_0$  were measured during each 0.5 s interval after the flash (1.5 s for first interval). The ratio (multi-IP<sub>3</sub>R patch/lone IP<sub>3</sub>R) is shown for both  $\tau_0$  and  $P_0$ . Results (means  $\pm$  SEM) are from 4 (single) and 7 (multiple, with 2–4 IP<sub>3</sub>R/patch) patches.

**Figure 4. Clustering retunes  $\text{Ca}^{2+}$  regulation of  $\text{IP}_3\text{R}$**

**a-e**, Patches were stimulated with PS containing  $10 \mu\text{M}$   $\text{IP}_3$  and (unless otherwise stated)  $1 \mu\text{M}$   $\text{Ca}^{2+}$ . **a**, Typical recording and summary data ( $n = 5-6$ ) from lone  $\text{IP}_3\text{R}$  show that increasing  $\text{Ca}^{2+}$  increases  $P_o$  by reducing  $\tau_c$ . **b**, Observed and expected numbers of  $\text{IP}_3\text{R}$ /patch. **c**, Observed and predicted  $NP_o$  for patches containing 1 or 2  $\text{IP}_3\text{R}$  and stimulated with  $10 \mu\text{M}$   $\text{IP}_3$  in PS containing  $200 \text{ nM}$  or  $1 \mu\text{M}$   $\text{Ca}^{2+}$  ( $n = 5-6$ ). **d**, Typical recording from a patch with 2  $\text{IP}_3\text{R}$ , enlarged (red) to highlight transitions directly between closed (C) and double open (O2) states. **e**, Observed and predicted  $P_o$  for closed (C) and single (O1) or double openings (O2) for patches with 2  $\text{IP}_3\text{R}$  ( $n = 6$ , Supplementary equations 4, 5). **f**, Observed and expected durations of events when both  $\text{IP}_3\text{R}$  are simultaneously open ( $\tau_{o,2}$ ) or closed ( $\tau_{c,2}$ ) for patches with 2  $\text{IP}_3\text{R}$  ( $n = 6$ , Supplementary equations 6, 7). **g**, Observed and predicted numbers of transitions to each of the 3 states in a patch with 2  $\text{IP}_3\text{R}$  ( $n = 6$ )<sup>26</sup>. **h**, At resting  $[\text{Ca}^{2+}]$ ,  $\text{IP}_3$  drives  $\text{IP}_3\text{R}$  into small clusters wherein  $\text{IP}_3\text{R}$  gate independently, but with reduced  $P_o$  and  $\text{IP}_3$  sensitivity.  $\text{Ca}^{2+}$  reverses the inhibition imposed by clustering, openings within a cluster are more synchronized, and simultaneous openings are prolonged. Clustering primes  $\text{IP}_3\text{R}$  to respond by repressing their activity, and then allowing  $\text{Ca}^{2+}$  to unleash the coordinated gating of clustered  $\text{IP}_3\text{R}$  (Supplementary Fig. 7).
