

Since January 2020 Elsevier has created a COVID-19 resource centre with free information in English and Mandarin on the novel coronavirus COVID-19. The COVID-19 resource centre is hosted on Elsevier Connect, the company's public news and information website.

Elsevier hereby grants permission to make all its COVID-19-related research that is available on the COVID-19 resource centre - including this research content - immediately available in PubMed Central and other publicly funded repositories, such as the WHO COVID database with rights for unrestricted research re-use and analyses in any form or by any means with acknowledgement of the original source. These permissions are granted for free by Elsevier for as long as the COVID-19 resource centre remains active.

<sup>‡</sup>Department of Cardiothoracic and Vascular Surgery, Montefiore Medical Center, Albert Einstein College of Medicine, Bronx, NY

**Objectives:** Cardiac injury has been reported in up to 20%-to-30% of patients with COVID-19, and severe disease can lead to cardiopulmonary failure. The role of mechanical circulatory support in these patients remains undetermined. The authors here aimed to determine the characteristics and outcomes of patients with COVID-19 requiring venoarterial extracorporeal membrane oxygenation (VA ECMO) or veno-arterial-venous (VAV) ECMO support.

**Design and Setting:** A multicenter, retrospective case series.

**Participants:** The cohort consisted of adult patients (18 years of age and older) with confirmed COVID-19 requiring VA ECMO or VAV ECMO support in the period from March 1, 2020, to April 30, 2021. Outcomes were recorded until July 31, 2021.

**Measurements and Main Results:** To show factors related to death during hospitalization, patients were grouped as survivors and nonsurvivors. Kaplan-Meier analysis was used to estimate 90-day in-hospital mortality. Overall, 37 patients from 12 centers comprised the study cohort. The median patient age was 44 years old (interquartile range [IQR], 35-52), and 12 (32%) were female patients. The duration of ECMO support ranged from 2-to-132 days. At the end of the follow-up period, 13 patients (35%) were discharged or transferred alive, and 24 patients (65%) died during the hospitalization. The cumulative in-hospital mortality at 90 days was 64% (95% confidence interval: 47-81). During the time from intubation to VA ECMO or VAV ECMO initiation (1 day [IQR 0-7.5] v 6 days [IQR 2.5-14],  $p = 0.0383$ ), body mass index (32 [IQR 26-36] v 37 [IQR 33-40],  $p = 0.009$ ), and baseline C-reactive protein (7.15 v 38.9 mg/dL,  $p = 0.009$ ) were higher in those who expired.

**Conclusion:** Only one-third of the patients with COVID-19 requiring VA ECMO or VAV ECMO survived to discharge. Close monitoring of at-risk patients with early initiation of ECMO with circulatory support may further improve outcomes.

The use of extracorporeal membrane oxygenation (ECMO) has been reported predominantly for refractory pulmonary failure from COVID-19, with estimates of 90-day mortality ranging from 37%-to-46%.<sup>3-5</sup> While these studies showed that ECMO use during COVID-19 is promising, its role in cardiopulmonary failure largely remains unknown. In such reports, the proportion of patients receiving venoarterial or veno-arterial-venous extracorporeal membrane oxygenation (VA ECMO or VAV ECMO) for combined heart and lung failure was only about 4%-to-6%, and reports focusing only on VA ECMO use during COVID-19 are scarce.<sup>6-8</sup>

Proponents of VA ECMO use propose that the early initiation for refractory cardiogenic shock in appropriately selected patients can lead to favorable outcomes.<sup>9,10</sup> Appropriate patients tend to be younger and have fewer comorbidities.<sup>10</sup> On the other hand, VA ECMO support is extremely resource-intensive, and many patients with COVID-19 can have multi-organ dysfunction, arguing against VA ECMO use.<sup>11</sup> Accordingly, the study authors performed a multicenter study to determine the characteristics, outcomes, and clinical factors associated with death during hospitalization in patients with COVID-19 supported with VA ECMO or VAV ECMO.

## Methods

This study was a multicenter, retrospective case series of patients aged 18 years and older, with COVID-19 confirmed via positive real-time reverse transcriptase-polymerase chain reaction assay, who received either VA ECMO or VAV ECMO support anytime between March 1, 2020, and April 30, 2021. Patients were divided into those who survived to transfer and/or discharge and those who did not survive the hospitalization.

Investigators at the data coordination site at the Montefiore Medical Center invited other centers for participation by directly contacting the surgical directors of mechanical circulatory programs. A data use agreement was mutually agreed upon between every participating center and the data-coordinating institution at the Montefiore Medical Center, Albert Einstein College of Medicine. The study was approved by the institutional review board at all of the participating centers, and informed consent was waived. The institutional review board approval was granted on April 5, 2020, under protocol number 2020-11375. A data capture tool was created using Research Electronic Data Capture (REDCap) for record entry by the participating centers. Data fields included demographic characteristics, laboratory parameters, ECMO characteristics, and patient outcomes. All data were anonymized. Before data entry, sites individually were familiarized with the data capture tool, and consistency was ensured by continuous technical support provided by the corresponding author at the data coordination center throughout the data collection period. To maintain accuracy, the data capture fields contained checks for validity, such as input masks and range rules for date fields and branching logic. Data consistency was maintained through built-in drop boxes with standardized responses. Records were inspected manually for data entry errors, such as those in date temporality, by the data-coordination center and rectified by sites before analysis.

Follow-up began at the time of ECMO placement and was completed until the time of discharge and/or transfer or in-hospital mortality. In-hospital follow-up was until July 30, 2021. The study authors used Kaplan-Meier curves to estimate the probability of in-hospital mortality at 90 days after ECMO placement. Patients were not censored at the time of any changes in ECMO configuration and retained their initial group classification to adhere to principles of original treatment intention. Additional outcomes that were reported included the development of secondary infections, deep venous thrombosis, stroke, limb ischemia, and renal failure requiring dialysis after ECMO placement. Causes of death during hospitalization also were reported.

Continuous data are reported as medians and interquartile ranges (IQR), and categorical data are shown as counts and percentages. The Mann-Whitney *U* test and the chi-square test were used to assess significant differences in quantitative and categorical variables, respectively. No data were imputed. Stata version 16 (Stata Corp, LLC, College Station, TX) was used for all statistical analyses.

## Results

### *Patient Characteristics*

The study cohort included 37 patients from 12 centers who were supported by either VA ECMO or VAV ECMO during the study period. The median age was 44 years old (IQR, 35-52), and 32% were female patients. Within the cohort, the median body mass index (BMI) was 36 (IQR, 31-38). Twenty-five (68%) patients had preexisting conditions, with 12 (32%) patients having hypertension and 11 (30%) with diabetes mellitus. Twenty-five (68%) patients were transferred from another center for ECMO placement, and 11 (30%) patients were supported by ECMO after having received cardiopulmonary resuscitation previously during admission. Eighteen (49%) patients had an echocardiogram performed prior to ECMO placement; 9 (50%) of whom had a left ventricular ejection fraction less than 40%. Fourteen (38%) patients were not prone prior to ECMO in the authors' cohort. Of those, 11 patients were also on vasopressors and presumptively were not prone due to hemodynamic instability. In the authors' cohort, the median time from intubation to initiation of any ECMO modality was 1 day (IQR, 0-5 days), whereas the median time from intubation to either VA ECMO or VAV ECMO was 6 days (IQR, 1-11 days). The duration of ECMO support ranged from 2-to-132 days. Inflammatory markers, including ferritin (1,024; IQR, 685-2,270 ng/mL), C-reactive protein (CRP) (14.7; IQR, 4.9-88.8 mg/dL), d-dimer (6.1; IQR, 3.5-1,112 mg/mL), and lactate dehydrogenase (744; IQR, 316-1,317 U/L), were highly elevated before ECMO placement.

### *Outcomes*

By the end of the follow-up period, 24 (65%) patients had died during the hospitalization, and 13 (35%) patients were discharged or transferred alive. The probability of death during

hospitalization at 90 days was 64% (95% confidence interval: 47%–81%) (Fig 1) Table 1 shows a comparison of the differences in the baseline demographic characteristics and laboratory parameters of patients who died and those who were discharged or transferred. Patients who expired had a higher BMI (37 [IQR: 33–40] v 32 [IQR 26–36],  $p = 0.009$ ), higher baseline CRP (38.9 v 7.15 mg/dL,  $p = 0.009$ ), and a longer time from intubation to either VA ECMO or VAV ECMO initiation (6 days [IQR: 2.5–14] v 1 day [IQR: 0–7.5],  $p = 0.038$ ).

The most common causes of death were multiorgan failure (8 patients; 33%), cardiac failure (4; 17%), and respiratory failure (2; 8%). For patients who were discharged or transferred alive, 6 (46%) were discharged to a rehabilitation facility, 5 (38%) were transported to another healthcare facility, such as long-term acute care or lower-acuity hospital, and only 2 (15%) were discharged to home (Table 2).

#### ECMO Characteristics and Course

Seventeen (46%) patients initially were cannulated as venovenous (VV ECMO), 15 (41%) as VA ECMO, and 5 (14%) as VAV ECMO. Fourteen (38%) patients eventually were switched to VAV ECMO (Fig 2). Patients receiving VA ECMO support had a mortality rate of 61%, while those placed on VAV ECMO had a mortality rate of 68%. Patients who were switched from VV ECMO to either VA ECMO or VAV-ECMO had a mortality of 82%, whereas patients supported by either VA ECMO or VAV ECMO only or switched from either VA ECMO or VAV ECMO to VV ECMO had mortality rates of 46% and 57%, respectively.

The most common location in the hospital for cannulation was at the bedside or in the intensive care unit procedure room (19 patients; 51%), followed by the operating room (14; 38%). Heparin was used for anticoagulation in

27 (73%) patients, argatroban in 5 (14%), and bivalirudin in 5 (14%) cases.

Secondary infections were common and occurred in almost half of the patients (46%). Of these infections, bacteremia (11 patients; 30%) and bacterial pneumonia (10; 27%) occurred most often, followed by urinary tract infections (3; 8%). Deep venous thrombosis was noted in 5 (14%) patients. Hemorrhagic stroke occurred in 3 (8%) patients, and ischemic stroke was noted in 2 (5%) patients. Renal replacement therapy was required in 19 (51%) patients. A lower proportion of survivors required renal replacement therapy (23% v 67%,  $p = 0.017$ ). Bleeding requiring transfusion was noted in 24 (65%) patients.

#### Discussion

The major findings of this multicenter case series of patients with COVID-19 requiring either VA ECMO or VAV ECMO support were as follows: (1) in-hospital mortality was elevated at nearly 65%; (2) switching from VV ECMO to either VA ECMO or VAV ECMO was associated with the highest mortality; and (3) patients who expired were placed on either VA ECMO or VAV ECMO at a later time from intubation in comparison to those who survived. Those who survived incurred significant morbidity, as only a minority were able to be discharged directly to their home.

This report found that patients with COVID-19 requiring ECMO for circulatory support had a significantly higher 90-day in-hospital mortality of 64% in comparison to 37%–to–46% reported in studies with nearly all patients requiring VV ECMO for respiratory support.<sup>3–5,12–14</sup> Although this study lacked a contemporary non-COVID-19 group, prior observational studies in non-COVID-19 patients with myocarditis requiring VA ECMO have reported lower mortality. In a meta-analysis of 170 patients, Cheng et al reported a pooled

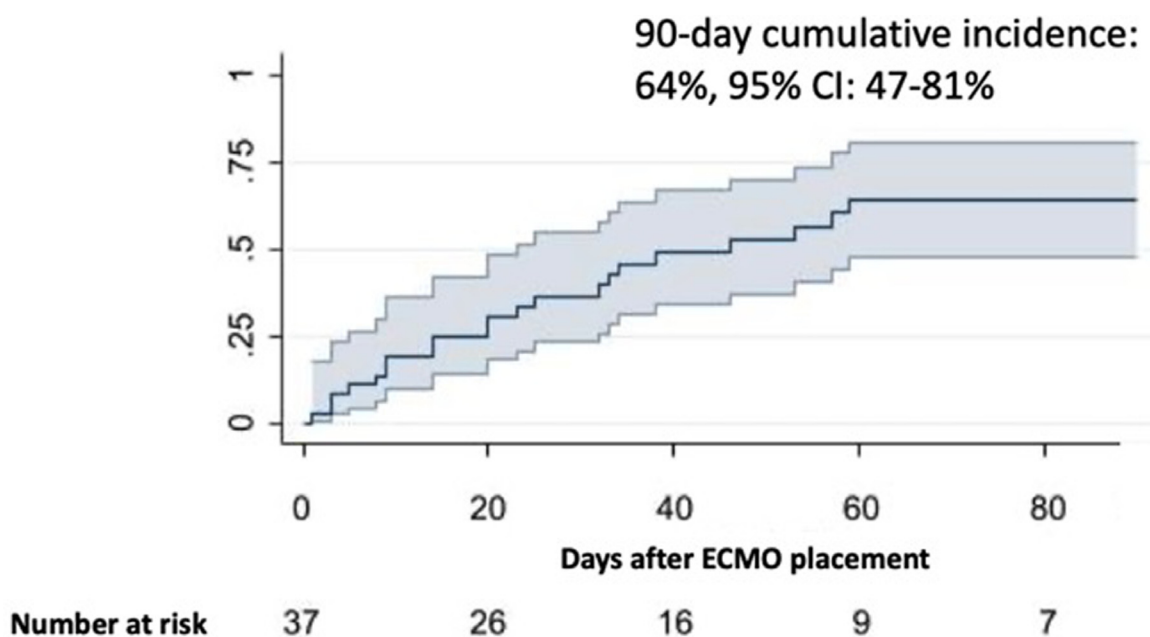

Fig. 1. Estimated cumulative incidence of in-hospital mortality after initiation of extracorporeal membrane oxygenation (ECMO) for COVID-19 at 90-days was 64% (95%CI: 47–81). The solid line shows the estimated cumulative incidence of in-hospital mortality and the shaded region represents the 95% CI.

\*Reported in 32 cases.

mortality of 33%, with similar age and sex distributions to those patients within the authors' case series here.<sup>15</sup> The indication for VA ECMO in those studies, however, primarily was to provide circulatory support, whereas patients with COVID-19 usually require both respiratory and circulatory support given the primary pulmonary pathophysiology of the disease. Due to the lack of invasive hemodynamic monitoring

and the absence of echocardiograms in most patients, the exact etiology of hemodynamic decompensation in the authors' cohort here could not be determined precisely and could have been cardiogenic, sepsis, vasoplegia, or mixed shock. Notwithstanding additional clinical confounders and patient selection, it is essential to identify methods to reduce mortality in patients with COVID-19 requiring VA ECMO.

Table 2

Abbreviations: ECMO, Extracorporeal membrane oxygenation; ICU, intensive care unit.

A subgroup of patients who were switched to either VA ECMO or VAV ECMO incurred higher mortality than those placed on circulatory support at the onset. Due to the limits of data collection, the study authors cannot determine if such patients developed cardiac failure after placement on VV ECMO or whether there was unrecognized cardiac dysfunction that eventually declared itself and necessitated mechanical circulatory support. Regardless, the higher mortality of this subgroup indicated that baseline risk stratification of impending cardiac failure with echocardiography and, if needed, invasive hemodynamics, is critical and may identify appropriate candidates for early arterial cannulation. This further was underscored with survivors showing a lower time to either VA ECMO or VAV ECMO in comparison to non-survivors.

Patients who expired were noted to have higher CRP and a higher BMI than patients who survived. While obesity has not been shown to be a negative prognostic factor in cardiogenic

shock requiring VA ECMO, this finding was consistent with literature showing obesity to be associated with increased risk of death from COVID-19 in adults younger than 65 years.<sup>16,17</sup> Higher CRP also has been associated with mortality in patients with COVID-19.<sup>18,19</sup>

Hematologic and neurologic disturbances occur with both COVID-19 and VA ECMO.<sup>20-22</sup> The authors noted a numerically higher burden of these adverse events during device support in comparison to prior studies of non-COVID-19 patients. The observed prevalence of bleeding (65%) and stroke (13%) were numerically higher in this series of patients in comparison to the reported rates of 40% and 6% during VA ECMO in non-COVID-19 patients, respectively.<sup>22</sup> This elevated burden of adverse events also may have contributed to greater mortality during ECMO support.

There were several limitations in this study. First, the authors' sample size was small. Second, the retrospective study design and the lack of a control group of non-COVID-19

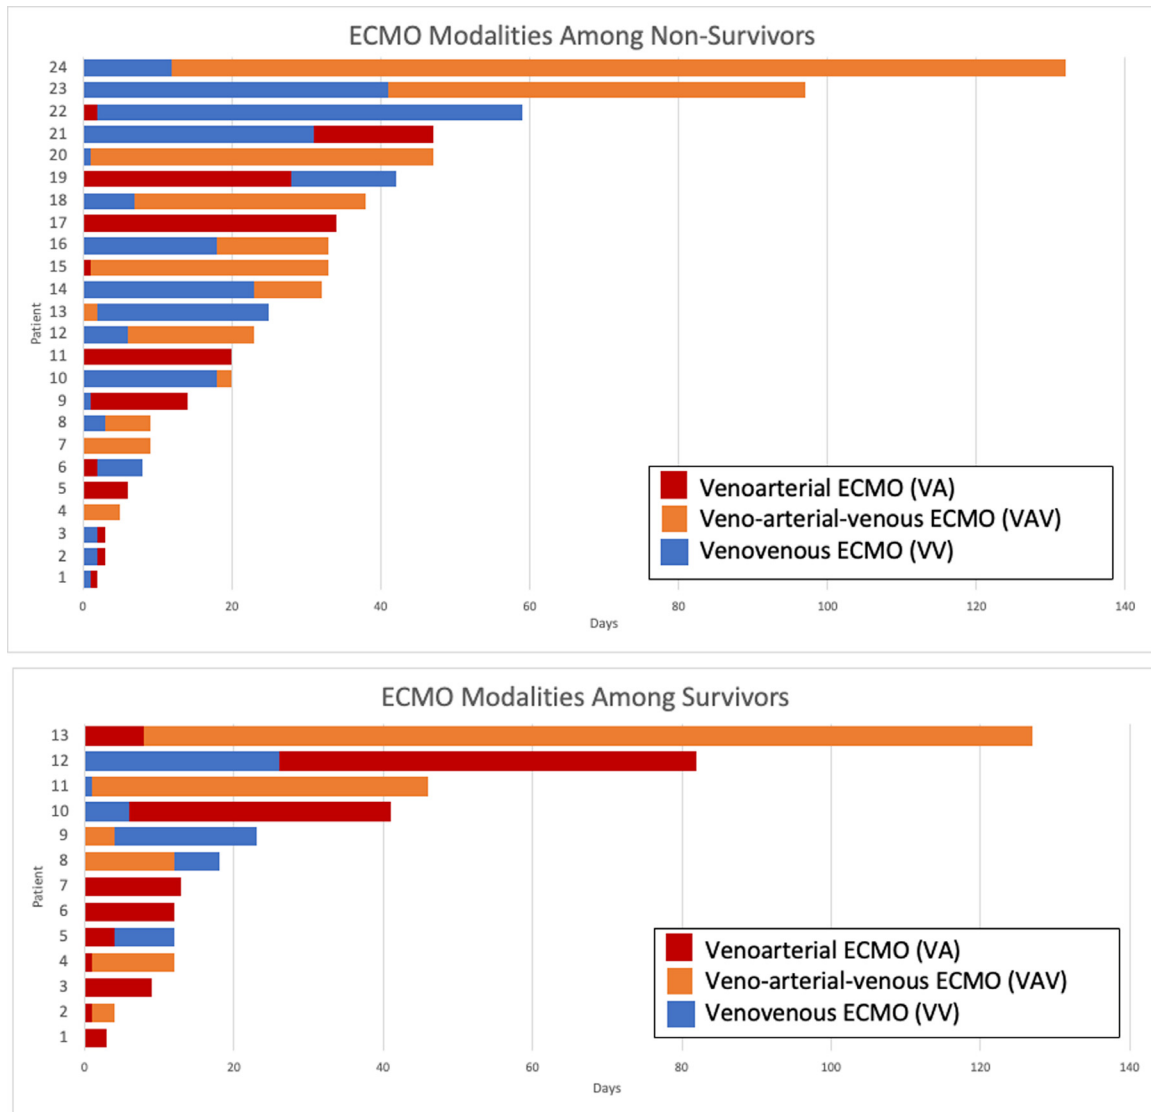

Fig. 2. Changes in the configuration of extracorporeal membrane oxygenation among survivors and non-survivors.

patients limited the interpretation of the findings. Third, outcomes from centers that participated in this study might not be reflective of those from institutions with different resource availability. There were no prespecified criteria for ECMO placement, and the decision to initiate mechanical circulatory support was institution-specific. Despite these limitations, the study shed light on a relatively understudied and extremely resource-intensive treatment modality in this pandemic.

In conclusion, this report showed that only one-third of patients with COVID-19 who received either VA ECMO or VAV ECMO survived. Methods to improve outcomes may involve close monitoring of at-risk patients with tenuous cardiac function, with the early initiation of ECMO with circulatory support in appropriate patients.
