## Abstract

Although a reduction in hospital admissions of acute coronary syndromes (ACS) patients has been observed globally during the coronavirus disease 2019 (COVID-19) pandemic, clinical features of those patients have not been fully investigated. The aim of the present analysis is to investigate the incidence, clinical presentation, and outcomes of patients with ACS during the COVID-19 pandemic. We performed a retrospective analysis of consecutive patients who were admitted for ACS at our institution between March 1 and April 20, 2020 and compared with the equivalent period in 2019. Admissions for acute myocardial infarction (AMI) reduced by 39.5% in 2020 compared with the equivalent period in 2019. Owing to the emergency medical services (EMS) of our region, all time components of ST-elevated myocardial infarction care were similar during the COVID-19 outbreak as compared with the previous year's dataset. Among the 106 ACS patients in 2020, 7 patients tested positive for COVID-19. Higher incidence of type 2 myocardial infarction (29% vs. 4%,  $p=0.0497$ ) and elevated D-dimer levels (5650  $\mu\text{g/l}$  [interquartile range (IQR) 1905–13,625  $\mu\text{g/l}$ ] vs. 400  $\mu\text{g/l}$  [IQR 270–1050  $\mu\text{g/l}$ ],  $p=0.02$ ) were observed in COVID-19 patients. In sum, a significant reduction in admission for AMI was observed during the COVID-19 pandemic. COVID-19 patients were characterized by elevated D-dimer levels on admission, reflecting enhanced COVID-19 related thrombogenicity. The prehospital evaluation by EMS may have played an important role for the timely revascularization for STEMI patients.

## Highlights

- The COVID-19 outbreak was associated with a 40% decrease in AMI.
- The delay of STEMI care was minimal in our center, suggesting that the healthcare system effectiveness was maintained despite the pandemic.
- ACS patients tested positive for COVID-19 was clearly characterized by elevated D-dimer levels on admission, reflecting enhanced COVID-19 related thrombogenicity.

## Introduction

In December 2019, coronavirus disease 2019 (COVID-19) infected pneumonia caused by severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) occurred in Wuhan,

China with further worldwide transmission to a pandemic outbreak [1–5]. A large cluster of COVID-19 occurred in northeast France as early as mid-February, and a substantial number of critically ill patients started to be transferred to our institution (Nouvel Hôpital Civil, Strasbourg, France) from the beginning of March. As a way to contain the disease, the government established stringent lockdown measures as of March 17, 2020. Although a drastic reduction in patient admissions for acute coronary syndrome (ACS) during the confinement was noticed by health workers [6, 7], clinical features of those patients have not been fully investigated [8]. In the present study, we aimed to evaluate incidence, clinical presentation, serial laboratory tests, and clinical outcomes of patients with ACS during the COVID-19 pandemic.

## Methods

We conducted a single-center, observational survey to collect data of all consecutive patients who underwent emergency angiography for suspected ACS between March 1 and April 20, 2020 and compared with the equivalent period in 2019. ACS was defined as ST-segment elevation myocardial infarction (STEMI), non-ST-segment elevation myocardial infarction (NSTEMI), or unstable angina pectoris. Symptom-onset-to-first medical contact (FMC) time was defined as the time from patient-reported chest discomfort onset time to the time of FMC. FMC-to-device time was defined as the time from FMC to successful wire crossing time during percutaneous coronary intervention. Door-to-device time was defined as the time from hospital arrival to successful wire crossing time. Catheterization laboratory (cath lab) arrival-to-device time was defined as the time from patient arrival in the cath lab to successful wire crossing time. Based on the World Health Organization guidance, a “confirmed case” of COVID-19 was defined by a positive test of a reverse-transcriptase–polymerase-chain-reaction assay of a specimen collected on a nasopharyngeal swab. The COVID-19 testing was performed based on the treating team’s discretion. The investigation conforms with the principles outlined in the Declaration of Helsinki.

## Statistical analysis

Categorical variables are expressed as numbers (percentage), and continuous variables are expressed as mean  $\pm$  SD or median and inter-quartile values. Differences between 2 groups were assessed with  $\chi^2$  tests or Fisher’s exact tests for categorical variables. Unpaired Student’s *t*-test was used to analyze continuous variables with normal distributions, and the Wilcoxon test was used to analyze continuous variables with skewed distributions. Propensity score matching

was used to limit the risk of error and the number of biases between the COVID and non-COVID patients. The 3:1 propensity score model was developed using logistic regression. This model included the following covariates: age, sex, STEMI, and NSTEMI. A nearest neighbor algorithm was used to match patients with and without COVID-19 in a 3:1 ratio, with a caliper width equal to 0.2 of the standard deviation of the logit of the propensity score. The propensity score matched cohort included a total of 20 patients (5 COVID-19 patients and 15 non-COVID-19 patients). *p* values of  $<0.05$  were considered to indicate statistical significance. All analyses were performed using JMP 13 software® (SAS Institute, Cary, NC) or R version 3.6.3 [9].

## Results

A total of 106 patients were enrolled from the 2020 period and compared with the 174 patients from the equivalent period in 2019 (Table 1). The number of patients with acute myocardial infarction (AMI) was dramatically reduced from 159 in 2019 to 92 in 2020 (39.5% reduction), whereas the number of patients with STEMI was similar (Fig. 1). Likewise, the number of patient admissions in the cardiology department was reduced by 42% after the French lockdown (Supplementary Fig. 1).

All time components of STEMI care were similar during the COVID-19 outbreak as compared with the previous year’s dataset (Fig. 2). Within the STEMI subgroup, no difference between the 2019 and 2020 cohort could be registered for in-hospital mortality rate (4% vs. 7%,  $p=1.00$ ), median length of hospital stay (4 days [interquartile range (IQR) 3–5 days] vs. 4 days [IQR 3–7 days],  $p=0.81$ ), troponin I levels at baseline (0.75  $\mu\text{g/l}$  [IQR 0.20–5.64  $\mu\text{g/l}$ ] vs. 1.61  $\mu\text{g/l}$  [IQR 0.16–6.59  $\mu\text{g/l}$ ],  $p=0.62$ ) and at peak (88.81  $\mu\text{g/l}$  [IQR 30.07–223.93  $\mu\text{g/l}$ ] vs. 81.08  $\mu\text{g/l}$  [IQR 40.68–155.80  $\mu\text{g/l}$ ],  $p=0.77$ ), baseline brain natriuretic peptide (BNP) levels (36 ng/l [IQR 21–79 ng/l] vs. 65 ng/l [IQR 31–246 ng/l],  $p=0.17$ ), and left ventricular ejection fraction (LVEF) at baseline ( $52 \pm 11\%$  vs.  $50 \pm 12\%$ ,  $p=0.62$ ).

Among the 106 ACS patients in 2020, 7 ACS patients tested positive for COVID-19. The clinical features of COVID-19 patients receiving cardiac catheterization for ACS are described in Table 2 and Fig. 3. ACS patients with COVID-19 tended to present with dyspnea (57% vs. 23%,  $p=0.07$ ) rather than chest pain (57% vs. 86%,  $p=0.08$ ). The incidence of STEMI and NSTEMI was similar between patients with and without COVID-19, whereas type 2 myocardial infarction (MI) was more frequent in COVID-19 patients (29% vs. 4%,  $p=0.0497$ ). Interestingly, not only C-reactive protein levels (70 mg/l [IQR 19–267 mg/l] vs. 4 mg/l [IQR 4–18 mg/l],  $p=0.006$ ) but also D-dimer levels at baseline (5650  $\mu\text{g/l}$  [IQR 1905–13,625  $\mu\text{g/l}$ ] vs. 400  $\mu\text{g/l}$

AF atrial fibrillation, ARDS acute respiratory distress syndrome, BMI body mass index, BNP brain natriuretic peptide, CABG coronary artery bypass grafting, COPD chronic obstructive pulmonary disease, COVID-19 coronavirus disease 2019, Cr creatinine, CRP C-reactive protein, eGFR estimated glomerular filtration rate, Hb hemoglobin, HDL-C high-density lipoprotein cholesterol, ICU intensive care unit, LDL-C low-density lipoprotein cholesterol, LVEF left ventricular ejection fraction, MI myocardial infarction, NSTEMI non-ST-segment elevation myocardial infarction, PCI percutaneous coronary intervention, POBA plain old balloon angioplasty, STEMI ST-segment elevation myocardial infarction, VF ventricular fibrillation, VT ventricular tachycardia, WBC white blood cell

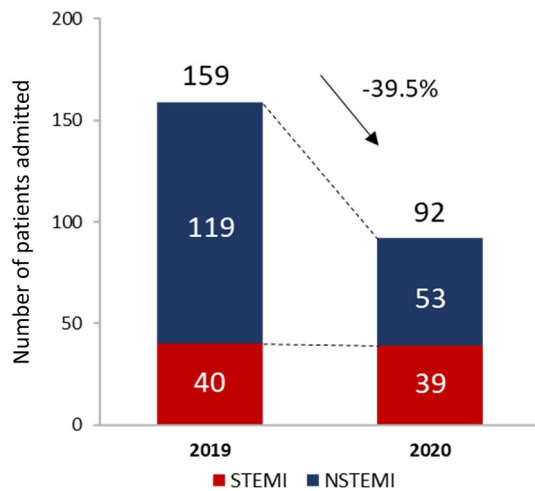

[IQR 270–1050  $\mu g/l$ ],  $p=0.02$ ) were significantly higher in COVID-19 patients than non-COVID-19 patients. COVID-19 patients had longer hospital stay (16 days [IQR 3–18 days vs. 4 days [IQR 2–6 days],  $p=0.03$ ) and higher incidence of acute respiratory distress syndrome (29% vs. 0%,  $p=0.003$ ) and venous thromboembolism (29% vs. 0%,  $p=0.003$ ). Further analysis utilizing 3:1 propensity score matching demonstrated similar trends in D-dimer levels, hospital length of stay and acute respiratory distress syndrome (ARDS), which did not reach statistical significance, probably due to the small number of patients included (Supplementary Table 1).

## Discussion

In the present study, the COVID-19 outbreak was associated with a 40% decrease in AMI. Similar findings have been noted in northern Italy and in the United States [10,

11]. The identification of the mechanisms leading to the reduction in admissions for AMI is beyond the scope of the present work. Nevertheless, recent reports suggested that the decreased number of ACS patients was due to the fear of exposure to COVID-19 affected subjects at hospital admission or a true reduction in the incidence of ACS as the potential result of low physical stress during the social containment [6, 12, 13].

The delay on STEMI reperfusion during the COVID-19 pandemic has been explained by the fact that the emergency medical system was focused on COVID-19 and a large number of healthcare workers was relocated to manage the pandemic, resulting in increased mortality and complications in STEMI patients [6, 14, 15]. In contrast, the delay of STEMI care was minimal in our center, suggesting that the healthcare system effectiveness was maintained despite the pandemic. Owing to the emergency medical services (EMS) of our region, more than half of

**Fig. 1** Numbers of myocardial infarction before and after COVID-19 pandemic. *COVID-19* coronavirus disease 2019, *NSTEMI* non-ST-segment elevation myocardial infarction, *STEMI* ST-segment elevation myocardial infarction

the STEMI patients continued to be directly referred to the cath lab according to prehospital electrocardiograms (60% vs. 73%,  $p=0.29$ ).

In the present study, patients tested positive for COVID-19 tended to have less chest pain and more type 2 MI. Prior investigations suggested that those patients may have hypoxemia or hypotension along with intense systemic inflammation, which may cause an oxygen supply and demand imbalance in the heart, especially when underlying CAD exists [16–18]. Moreover, COVID-19 patients were clearly characterized by elevated D-dimer levels on admission in the present study, reflecting enhanced COVID-19 related thrombogenicity [19–22]. Although the increased thrombotic susceptibility in COVID-19 patients are far beyond the scope of this study, prior studies underlined that higher thrombotic burden in the acute phase of COVID-19 relies on pro-inflammatory cytokine/chemokine release [23], increased endothelial dysfunction/damage, and potential sepsis induced coagulopathy development in severe cases, all promoting coagulation activation. A recent observational study

including 115 STEMI patients clarified that COVID-19 patients had an elevated D-dimer levels as well as higher thrombotic burden compared to non-COVID patients [24]. Our study described lower PCI rate and higher incidence of venous thromboembolism and ARDS in the COVID-19 patients (Table 2), suggesting that those complications may have led COVID-19 patients to present ACS like symptoms. These insights may pave the way toward a novel diagnostic perspective for ACS patients complicated to COVID-19.

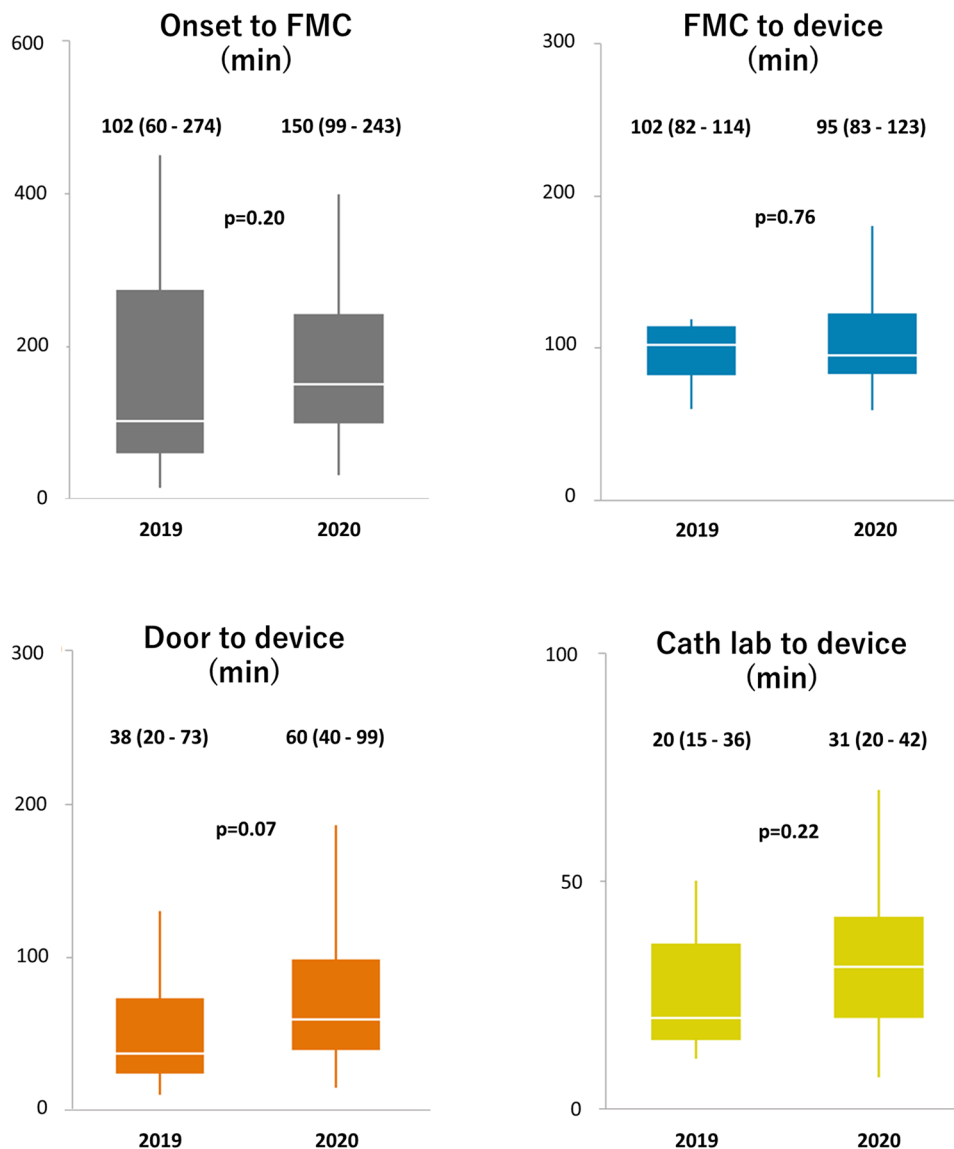

### Study limitation

We acknowledge the following limitations: First, the analyses were performed on the basis of a single center data set with uncertain generalizability. Second, owing to the retrospective nature of this study, there were inherent limitations related to confounding known or unknown factors. Third, the study period was limited to 7 weeks based on the pandemic period in our region. The use of such a limited period for data collection may represent a source for potential bias. Forth, the effect of the low event rate might have been more pronounced when analyzing small subgroups. Fifth, the incidence of diagnostic testing was only 27% in the non-COVID-19 group, suggesting that certain asymptomatic COVID-19 patients may have been mis-classified. Sixth, a large proportion of COVID-19 patients complicated by AMI was not due to coronary obstruction but due to increased thrombogenicity and/or inflammation. The true effects of COVID-19 on coronary arteries should be identified by a larger cohort.

### Conclusions

In conclusion, a significant reduction in admission for AMI was observed during the COVID-19 pandemic. The prehospital evaluation by EMS may have played an important role for the timely revascularization for STEMI patients. Further studies are needed for the establishment of a dedicate diagnostic pathway for ACS patients with COVID-19, aimed at minimizing healthcare providers risk of infection.
