Published: 4 Aug 2020

Abstract

Background: Exosomes are extracellular cells (EVs) emancipated by various cell types and are involved in cell-to-cell transmission. In cancer diseases, exosomes emerge as local and systemic cells to cell mediators of oncogenic information and play a significant role in the advancement of cancer through the horizontal transfer of various molecules, such as proteins and miRNAs.

Methods: In this study, 66 articles from PubMed, MEDLINE, Science Direct, Cochrane, EMBASE, and Scopus were used as English sources.

Results: The biological distribution of cancer cell-derived exosomes in tumor tissue is an important factor in detecting their role in tumor increase; on the other hand, a limited number of studies have examined the biodistribution of exosomes in tumor tissues. While exosomes function as cancer biomarkers and support cancer treatment, we have a long way to improve the antitumor treatment of exosomes and develop exosome-based cancer diagnostic and therapeutic strategies.

Conclusion: This review describes the science and significance of cancer pathogenesis and exosomes relative to cancer treatment resistance.

Introduction

Two different research groups, led by Philip Stahl and Rose Johnstone, independently described reticulocyte fusion back into reticulocyte plasma membranes, and exosomal cargoes were discovered 35 years ago (1). Interestingly, the secretion of exosome mechanism was demonstrated in a study about the iron-binding transferrin receptor by reticulocytes during maturation into erythrocytes in 1983 by Harding et al (1). The downregulation of transferrin receptors was considered as related to endocytosis and lysosomal degradation and revealed the multivesicular bodies and fusion with the plasma membrane (2). In recent

years, a mechanism for intracellular communication involving the extracellular transfer of extracellular vesicles (EVs) has emerged. EVs are composed of both microparticles produced by reverse budding of multi membrane bodies, spilling from the plasma membrane released from nanovesicles or exosomes. The microgranules are produced directly from the cell plasma membrane from external cell budding (3). Although the release of apoptotic bodies during apoptosis has been known for a long time (4), the fact that perfectly healthy cells pour vesicles through plasma membranes has only recently been recognized. Most cells,

This review describes the current science and significance in cancer pathogenesis and exosomes relative to cancer treatment resistance.

including normal and diseased cells, can release the bilayer membrane-bound nanovesicles into the extracellular space and body fluids. EVs derived from this membrane can be divided into 3 main classes depending on their size, following exosomes (40-100 nm), microparticles (100-500 nm), and apoptotic bodies (500-1000 nm). Exosomes are distinguished from apoptotic bodies and microparticles according to their size, origin, and composition. The apoptotic vesicles appear when the cells enter apoptosis as a result of the signals they receive from their environment (5). The protein content of EVs from different sources was analyzed by SDS-PAGE, followed by protein staining, immunoblotting, or proteomic analysis. In highly purified EVs, protein proteins of serum proteins and intracellular compartments (eg, the endoplasmic reticulum or mitochondria) should never contain contaminants that do not come into contact with EVs. As a result, exosomes from different cell types include endosome-related proteins (eg, Lord GTPase, SNAREs, Supplements, and flotillin), some of which are involved in MVE biogenesis (eg, Alix and Tsg101) (6). Membrane proteins, which are known to accumulate in microregions in the plasma membrane or endosomes, are also enriched in EVs. These include tetraspanins, a family of >30 proteins consisting of 4 transmembrane domains (7-9). The molecular composition of exosomes depends on the cell type of origin, but most exosomes contain highly concentrated molecules. Tetraspanins are the most abundant protein family found on exosomes. Tetraspanin is a highly conserved membrane protein between species, which spans the membrane four times and act as scaffolding proteins, anchoring multiple proteins to a location on the plasma membrane (8, 9). The tetraspanins CD9, CD63, CD81, CD82, and CD151 are highly enriched on exosomes in a similar way as lipid rafts (10). Zöller showed that tetraspanins are very important in EVs from other sources (11). Although tetraspanin-enriched membrane regions are different from detergent-resistant lipid, protein rafts, EVs are also

enriched in proteins coupled to lipid rafts, including glycosylphosphatidylinositol-associated proteins and flotillin (12, 13) (Fig. 1).

In place of, they are formed by inward budding of the endosomal membranes, thereby resulting in the formation of intracellular multivesicular bodies combine and secreted with the plasma membrane (14). Exosomes include blood plasma/serum (15), saliva (16), breast milk (17), cerebrospinal fluid (18), urine, and semen (19). Exosomes are secreted from healthy cells in physiological conditions as well as by cancer cells and tumor-associated stromal cells (20, 21). It has been shown that exosomes play an important role in the regulation of immune responses in both innate and adaptive immunity. Exosomes are involved in the spread of self and nonself antigens to many sites of the body due to their small size. Exosomes that are secreted from antigen presenting cells (APCs) such as B cells and dendritic cells (DC) can activate T-cells by direct binding of exosomal MHC-peptide complexes to the T-cell receptor. Also, antigen-bearing exosomes can be internalized and processed by APCs, to activate T-cells (21). Additionally, the origin of the exosomes determines the impact, as mature DC exosomes induce T-cell activation more effectively than immature DC exosomes (20, 21). Moreover, exosomes derived from mycoplasma infected DCs could induce both T-cell and B-cell proliferation. Additionally, exosomes derived from mycoplasma infected DCs could induce both T-cell and B-cell proliferation (22). Exosomes are associated with various antigens according to the disease or infection type. Pathogen-infected cell exosomes carry pathogen-specific antigens, which can be processed and associated by DCs to activate T-cells. Furthermore, it has been demonstrated that tumor-derived exosomes can also be processed by DCs and provide antitumoral immune responses by activating T-cells through the presentation of tumor-specific antigens (22, 23). The purpose of the article significant in

cancer pathogenesis and exosomes relative to cancer treatment resistance.

Effects of EVs on Suppression of immune responses

There is great evidence that immune responses are induced by antigen-containing EVs, the release of EVs by tumor cells is a mechanism by which tumors suppress the anti-tumor immune response. Injection of tumor-derived EVs bearing tumor antigen Ovalbumin (OVA) results in the suppression of delayed-type hypersensitivity (DTH) response to OVA (24). Tumor EVs are likely to be acquired by endogenous APCs that suppress the immune response following the footpad injection of OVA. Similarly, injection of tumor-derived EVs partially induced IL-6 expression in these leader cells by inhibiting the differentiation of CD11b⁺ myeloid precursors in the bone marrow (25, 26). These myeloid cells have also been shown to alter their pathways of differentiation into a myeloid-derived suppressor cell (MDSC) phenotype (27). Here, some miRNAs found in prostaglandin E2 (PGE2), heat shock protein (HSP70), and tumor-derived EVs play a major role in directing monocyte differentiation towards MDSCs. Also, there is an increase in transforming growth factor beta (TGF- β) expression by myeloid cells that contributes to antigen-specific immunosuppression (27). Interestingly, EVs isolated from the serum of tumor-bearing mice can suppress the immune response to a specific tumor antigen by a mechanism linked to major histocompatibility complex (MHC) class II molecules (MHC-II) (28). Here, the suppression of the antigen-specific immune response is not carried out by tumor-derived EVs, but by CD11b⁺, MHC class II⁺ host-derived EVs. Thence, in the tumor microenvironment, tumor EVs are assumed to be taken up by macrophages and possibly other APCs and receive EVs that can suppress immune responses to tumor antigens present in tumor EVs. Taken together, these results show that not only tumor-derived EVs can directly suppress T and natural killer (NK) immune responses, but can also indirectly suppress responses through macrophage cross-presentation and subsequent release of EVs (27).

Exosomes in cancer detection

Exosomes have been identified in many biological fluids, described in this review above. Cancer exosomes can serve as a fluid biopsy to aid in the diagnosis of malignancies including cancers of the prostate, pancreas, breast, and ovary, glioblastoma, and melanoma (28). Increased exosome concentration has been reported in patients with ovarian, breast, and pancreatic cancer (16). Specific markers associated with cancer exosomes may enhance their enrichment and may be useful for diagnosis when collected from a heterogeneous exosome population in body fluids. In vitro or ex vivo While lipids and metabolites in cancer exosomes provide unique information about cancer detection and biology, more precise information is being developed on the use of proteins and nucleic acids in the exomes. EVs may play an immunosuppressive or immunostimulatory role (7, 8). C-phosphate-G (CPG) has been shown to stimulate B cells from HIV patients to produce lower amounts of IgG

in the presence of EVs from the same patients. Platelet-derived EVs are biased to the secretion of growth factor-secret which causes an anti-inflammatory response and transformation of macrophages. However, exomes containing auto-immune antigens are immunostimulatory in a NOD mouse model and lead to the production of proinflammatory cytokines and the proliferation of T cells (10). Cancer cell-derived exosomes play a role in determining the tumorigenic potential of epithelial cells (24, 25). Cancer ex vivo miR may also contribute to tumor formation and can mediate cell-independent miR biogenesis, which is a feature not associated with normal exosomes. Exosomes with cancer RNA-induced silencing complex-associated miRs induce tumor formation by non-tumorigenic mouse breast cells (MCF-10A cells). In particular, disruption of exosome-associated miR biogenesis by specific silencing of Dicer prevented the growth of MCF10A tumors (25).

Exosomes in tumor angiogenesis

Exosomes are also involved in the regulation of pathological angiogenesis, including tumor angiogenesis (29). Especially in response to enhanced exosome production due to intratumoral hypoxia, the uptake of cancer cell-derived exosomes by endothelial cells (ECs) stimulates angiogenesis (30). This is achieved in part by stimulating the proangiogenic secretome of ECs (31). Angiogenic programs initiated by hypoxia-induced cell signaling in cancer cells may be affected by exosomes. The effect of tumor-derived exosomes on vascular remodeling can affect not only tumor growth but also metastasis. For example, melanoma-derived exosomes cause vascular leakage at sites of metastasis and affect the pro-vasculogenic phenotype of recruited bone marrow (BM) progenitors (32). Cancer cell-derived exosomes may also impair the structural integrity of ECs. The uptake of cancer cell-derived exosomal miR-105 by ECs lowers the tight junction protein ZO-1, thereby enhancing vascular permeability and metastatic spread (33).

Effect of exosome in cancer immunotherapy

Immunotherapy of cancer has recently become one of cancer prevention strategies, particularly for patients who do not respond to conventional treatments (34). These exosomes carried by molecular can be immunostimulatory or immunosuppressive and respectively exosome interactions with the host immune system can lead to a better or worse anti-tumor immune response at the result. Since that is useful for the tumor to suppress anti-tumor immunity, tumor immune microenvironment (TME) will likely support immunosuppression. For this purpose, it is not the only participate in blinded anti-tumor immune responses assembled by the host using the various mechanisms but also interferes with and inhibits anti-tumor immune therapies. Exosomes have recently been shown to exert great effects on immunological activities as mediators involved in many stages of immune and inflammatory responses such as induction, orchestration, subtraction, dissolution, and regulation. As an important example, T regulatory (Treg) Foxp3⁺ cells produce exosomes that suppress type 1 T helper (Th1) cell proliferation and cytokine production by gene silencing due to

transferred Treg cell-derived miRNAs (27). Also, thymic epithelial cells produce tissue-restricted Antigen-bearing exosomes it directs the improving of Treg cells (28). An illustrative example of allergy relates to CD23⁺ (Fc-εR-2⁺) B cells and then produces exosomes that produce exosomes carrying CD23, IgE, and MHC-class II (B cell exosomes called "bexosomes"), which is transferred to DCs that stimulate antigen-specific T cells (28, 35). Exosome-mediated intercellular interactions involving mast cells are particularly relevant to allergies. These include T-cell exosome activation of mast cells and mast cell activation of T and B cells (36, 37), exosome-mediated phenotypic and functional maturation of mast cells (30, 38), and endothelial cells or progenitor stem cells (39). These effects can be induced by mast cell exhaust transfer of mRNA encoding exosome-mediated cytokines (36, 40) or cytokines and by influencing cytokine signaling (40) or by triggering cytokine production by bronchial cells (41) or airway smooth muscle cells (42). Finally, mast cell exosomes induce phenotypic and functional maturation of DC, enabling them to elicit specific immune responses in vivo, activate endothelial cells to secrete endothelial cells clotting factors, and activate T and B cells (36, 37). Exosomes also participate in various pathological processes such as tumor growth and metastasis, as well as chronic inflammation and infections (43). The list of human diseases mediating pathology is HIV-1 (44), autoimmunity (45), Parkinson's disease (46), Alzheimer's disease (46), numerous inflammatory conditions (47), and others. Perhaps of particular importance to the pathological role of exosomes is their effect on the host immune system. Exosomes produced by malignant or virus-infected cells carry an immunosuppressive cargo and cause dysfunction of the immune effector cells not only locally but also systemically at the site of the disease.

Tumor-derived exosomes suppress immune responses and help advance cancer

During cancer (tumor) development and metastasis, most cancer cells are opposed by the immune system. Suppressing immune reactivation or escaping immune surveillance is a vital task for cancer development. In this process, exosomes produced by both immune and non-immune cells play an important role in regulating host immunity. Most cancer patients have immunosuppression or immunodeficiency. Recently, immunotherapy plays an important role in many cancers such as malignant melanoma, kidney cancer, liver cancer, and even non-small cell lung cancer (48). In this section, we will discuss how exosomes alter the immunoactivity of cancer patients to help cancer cell development. Although tumor exosomes (which) express tumor antigen leading to their recommended use as tumor vaccines, these exosomes also provide antigen-specific immunosuppression (49). A lot of evidence shows the role of exosomes in immunosuppression (50, 51). For example, exosomes of OVA expressing melanoma containing full-length OVA protein can effectively suppress an OVA-specific immune response (52). In a tumor-bearing model, plasma-derived exosomes positive for CD11b suppressed the tumor antigen-specific response via an MHC class II-linked mechanism (53). The detailed mechanisms of exosomes in

suppressing tumor antigen-specific responses have been extensively studied. Tumor-derived exomes not only inhibit the immune activity of multiple lymphoid cell types but also modulate NKG2D expression in cancer to provide immune avoidance (53, 54). NKG2D is an activating receptor for NK, NKT, and CD8⁺ T cells, and down-regulation of expression or loss in cancer cells is a key mechanism underlying immune avoidance. An important study from Clayton (55) showed that exosomes produced by various cancer cell lines in vitro or isolated from pleural effusions of mesothelioma patients carry NKG2D ligands. These exosomes can trigger the down-regulation of surface NKG2D expression in NK cells and CD8⁺ T cells. Therefore, lymphocyte activation through NKG2D is impaired after exosome treatment. Furthermore, its interaction with NKG2D ligand positive tumor exosome lymphocytes did not lead to the activation of CD8⁺ T or NK cells. NKG2D down-modulation was due to CD8⁺ T of TGFβ1 or direct exosomes distribution of the NK cell subset (55).

Therapeutic use of exosomes for cancer

Reports have shown that various clinical studies have demonstrated the role of exosomes as cancer therapies and that several essential side factors have been identified in the application of these nanovesicles in cancer addition. There are effective methods for cancer treatment, for instance, chemotherapy, radiotherapy, hormone therapy, and target therapy. Bone marrow cells, such as breast cancer cells, hair follicle cells, and rapidly dividing cells, are the targets of chemotherapy and radiotherapy (35). Patients with positive estrogen receptor and progesterone receptor have been used hormone therapy (40). The two treatments are limited to side effects on normal cells; therapeutic effects and unpredictable responses. It is also responsible for treatment failure in drug resistance. Exomes with endogenous nano-sized membrane vesicles can be used to transport drugs with low immunogenicity and toxicity (31). After modification targeting breast cancer cells, exosomes can be used to give doxorubicin (dox) (33). Exosome derived from epigallocatechin gallate may prevent infiltration of tumor-associated macrophages and polarization of M2 macrophages and thus suppress cancer growth (32). Exosomes have worsened the potential for cancer growth in the tumor microenvironment. Immune escape is an important feature of cancer. Exosomes can transfer anti-tumor substances to ensure the surveillance of the immune system. Exomes released by an adenoviral vector (AdVHER2) showed HER2-specific cytotoxic T lymphocyte responses and dendritic cells (56), which have been shown to confer protective immunity against trastuzumab-resistant breast cancer. It is not appropriate to obtain a large number of exosomes due to the low exosome. Therefore, researchers should look for better methods to produce abundant exosomes without showing large costs. This is also controversial the way exosomes enter the body. Intravenous injection is appropriate, but exosomes should be directed to cancer cells, which is a challenge for exosome design. Avoiding this problem of targeted delivery design with local injection but that is new challenges (57). Exact secretion of exosomes triggers

changes in the local and systemic tumor environment to induce tumor cells, tumor growth enhancement, metastasis, and insensitivity to drugs. Thus, the destruction of the exosome-propagation pathway through the tumor cells or the removal of these nanovesicles from the blood circulation system can create an effective method of treating cancer (58). Recently, a therapeutic hemofiltration process called ADAPT™ (adaptive dialysis-like affinity platform technology) has been applied to remove EVs from the bloodstream (59). When the patient's blood plasma samples are transferred via the ADAPT™ system, the plasma sample factors of the porous fibers are particularly absorbed when interacting with immobilized affinity agents for these target molecules, particularly unbound serum factors and blood cells passing through this system (59). Exosomes are used as vehicles loaded with numerous anticancer drugs, siRNA, and miRNA for many cancer therapeutic burdens. The lipid bilayer membrane of these nanovesicles forms a natural protective shelter, thereby enhancing cellular internalization of encapsulated anti-cancer drugs. For exosomes originating from autologous cancer cells, these nanovesicles may cause minimal toxicity when introduced into target cells and may be less immunogenic than artificial delivery devices. Also, their small size may allow them to escape phagocytosis via the mononuclear phagocyte system (MPS) and can simplify their extravasation through tumor blood vessels and then release in target cancer tissues. Increased colorectal and breast cancers can be suppressed by administering doxorubicin-loaded on exosomes *in vivo* or using exosome-mimetic nanovesicles. Therefore, the effectiveness of doxorubicin has been extensively supported by targeting immature dendritic cell exosomes to cancer tissues (60). Also, another widely used antimetabolic chemotherapeutic drug is Paclitaxel, which can be loaded into microparticles by sonication, and these charged microparticles have 50 times more cytotoxicity than free Paclitaxel for drug-resistant tumor cells *in vitro*. Besides, the exosomes encapsulated Paclitaxel can substantially block murine Lewis lung cancer, metastases and reduce the size of a tumor in the mouse model (61). Exosomes can be used to target specific tissues or organs since they have specific cell tropism according to their properties. The application of a well-characterized exosomal membrane protein (Lamp2b) to express the targeting peptide immediately below the signal peptide sequence containing the targeting peptides rabies viral glycoprotein (RVG) and internalizing RGD (iRGD) was inserted into these nanovesicles to the target brain or cancer tissues from immature dendritic cells (59, 60). In addition to anti-cancer therapeutic drugs, exosomes can likewise include several tumor antigens, nano sized, apoptotic-containing proteins, proteasomes, deficient or mutant anti-apoptosis proteins, tumor and tissue-specific peptides, transferrin and lactoferrin in tumor cells for targeting drug (61-65). Exosomes-based cell-free vaccines may indicate alternative dendritic cell therapy to inhibit tumor growth through the function of exosomes in the immune system. These DC-derived exosomes contain costimulatory molecules on MHC-peptide complexes and membranes, that enable them to continue APCs and in-

crease immunization in mice compared to antigen-presenting dendritic cells (64). Furthermore, miRNAs are commonly assigned in exosomes in derived cancer cells or isolated from body fluids that contribute to exosome-mediated cell-cell communication and induce anti-cancer properties (65, 66).

Conclusion

Exosomes are an important player in cancer formation and progression due to their biological and morphological features. The facts that they differ according to the cell types they are originated and can be obtained from all fluids in the body are a serious advantage and potential markers for cancer-related studies. Endogenous EVs probably modulate immune responses while stimulating immune responses to antigens, suppressing self-response to antigens. Although EVs can modulate the function of many immune cell types, including T and NK cells, the most effective regulatory activity of EVs is achieved by binding or internalizing the cell surface via APCs. In cancer, tumor-derived exosomes carry a large number of immunosuppressive signals, disable anti-tumor immune effector cells, and promote tumor escape from immune control. In cancer, viral infections, autoimmune or other diseases, exosomes that give negative signals to immune cells can interfere with treatment and affect the outcome. However, the fact that exosome biology has not been fully enlightened yet poses a potential obstacle in future studies. In the light of the developing technology, exosomes are thought to be a nano biological structure that deserves to be investigated not only in the formation, progression, diagnosis, and treatment of cancer but also in studies on the mechanism and diagnosis of many diseases.
