# Inactivation and sub-lethal injury of *salmonella typhi*, *salmonella typhimurium* and *vibrio cholerae* in copper water storage vessels

Riti Sharan<sup>1†</sup>, Sanjay Chhibber<sup>2†</sup> and Robert H Reed<sup>1\*</sup>

## Abstract

**Background:** This study provides information on the antibacterial effect of copper against the water-borne pathogens *Salmonella Typhi*, *Salmonella Typhimurium* and *Vibrio cholerae*.

**Methods:** Suspensions of each pathogen were kept in water within a traditional copper vessel at 30°C for 24 h. Samples were withdrawn, diluted and plated onto suitable growth media. Conventional enumeration of healthy (uninjured) bacteria was carried out using standard aerobic incubation conditions. Additionally, reactive oxygen species-neutralised (ROS-n) conditions were achieved by adding the peroxide scavenger sodium pyruvate to the medium with anaerobic incubation, to enumerate uninjured (ROS-insensitive) and injured (ROS-sensitive) bacteria. Differences between log-transformed means of conventional (aerobic) and ROS-n counts were statistically evaluated using *t* tests.

**Results:** Overall, all three pathogens were inactivated by storage in copper vessels for 24 h. However, for shorter-term incubation (4–12 h), higher counts were observed under ROS-n conditions than under aerobic conditions, which demonstrate the presence of substantial numbers of sub-lethally injured cells prior to their complete inactivation.

**Conclusions:** The present study has for the first time confirmed that these bacterial pathogens are inactivated by storage in a copper vessel within 24 h. However, it has also demonstrated that it is necessary to account for short-term sub-lethal injury, manifest as ROS-sensitivity, in order to more fully understand the process. This has important practical implications in terms of the time required to store water within a copper vessel to completely inactivate these bacteria and thereby remove the risk of water-borne disease transmission by this route.

## Background

According to the World Health Organization, an estimated 4.1% of the total global burden of disease is contributed by diarrhoeal illness: around 88% of that burden is due to unsafe water supply, sanitation and hygiene, with children in developing countries being the most common victims [1]. Though there has been improvement in providing safe drinking water in developing nations such as India, the adverse impact of unsafe water continues. Today, inadequate access to clean drinking water and sanitation are among the biggest environmental problems in

India, threatening both urban and rural populations; children suffering from microbial contamination of drinking water supplies are exposed to a range of viral, bacterial and protozoal pathogens [2–4].

Among the water-borne pathogenic bacteria prevalent in developing nations, *Salmonella enterica* is of considerable significance, with approximately 22 million cases of enteric fever caused by *Salmonella Typhi* in 2002 [5] and approximately 5.5 million cases of enteric fever caused each year by *Salmonella Paratyphi A, B or C* [6]. In a study conducted on urban drinking water supply systems in Nepal, *Salmonella* was detected in 42 out of 300 water samples, with the predominant serotype being *Salmonella Typhimurium* [7]. Typhoid fever is one of the main public health problems in urban slums in India [5]. In a 2006 study in Kolkata, it was observed that typhoid fever mainly

Full list of author information is available at the end of the article

occurred in younger men, and that the absence of hygienic habits such as hand washing was a major route of transmission [8]. Similarly, cholera outbreaks have been reported from rural areas in India with unhygienic environmental conditions, inadequate sanitation and unsafe water supplies [9] and toxigenic strains of *Vibrio cholerae* O1 has been responsible for many large water-borne outbreaks of cholera on a global scale [10].

Ancient scriptures dating back to around 2000 BC highlight various practices of water treatment by filtration, exposure to sunlight and storage in brass and copper vessels [11]. Consequently, the antibacterial potential of copper has been exploited since these ancient times. In contrast to the low sensitivity of human tissue to copper, microorganisms generally are extremely susceptible to copper, making it suitable for water disinfection [12]. Previous studies have investigated the inactivation and injury of faecal indicator bacteria such as *Escherichia coli* and *Enterococcus faecalis* during short-term storage in brass vessels [11,13], with reactive oxygen species-neutralized (ROS-n) conditions consistently giving higher counts than aerobic counts indicating that conventional plate counting is not sufficient to enumerate sub-lethally injured bacteria. A study from south India [14] also described decreased bacterial contamination of water stored in a brass container, though without investigating the potential effects of sub-lethal injury. More recent research has reported the inactivation of *E. coli*, *S. Typhi* and *V. cholerae* after overnight storage in a copper vessel [15] though, again, the possibility of sub-lethal injury and lack of growth of injured cells under conventional enumeration conditions was not considered.

There are several reports of *V. cholerae* entering a dormant or a viable-but non-culturable (VNC) state due to nutrient deprivation and/or stressful environmental conditions [16,17]. However, an alternative explanation for the VNC state involves sub-lethal injury, as demonstrated for *Salmonella* Typhimurium following thermal and non-thermal food preservation procedures, where sub-lethal injury was demonstrated by plating on different selective media such as trypticase soy agar and violet red bile glucose agar, with the latter giving lower counts [18]. Conventional microbiological enumeration practices using aerobic culture does not take into account sub-lethal injury of the bacteria, which can be demonstrated through ROS-neutralisation techniques.

The present study was designed to investigate not only the dynamics of inactivation of *S. Typhi*, *S. Typhimurium* and *V. cholerae* in water stored in copper vessels but also to quantify the extent of any sub-lethal injury caused to these bacteria during storage in the vessels. Such sub-lethal injury is manifest in terms of ROS-sensitivity and counteracted using ROS-n enumeration conditions [19]. The findings of the present study have important

implications in relation to the practical use of copper vessels in rural areas of India and elsewhere, in terms of the time required to completely inactivate both healthy and injured bacteria.

## Methods

### Bacterial strains and culture preparation

*S. Typhimurium* MTCC1251 and MTCC98, *S. Typhi* MTCC733 and *V. cholerae* MTCC3906 were obtained from Institute of Microbial Technology, Chandigarh while *S. Typhi* Ty2 and *V. cholerae* O1 were obtained from the Central Research Institute, Kasauli. All strains were studied at Panjab University. Stocks were maintained by sub-culturing every 15-20 days on nutrient agar (HiMedia, Mumbai, India). For experimental procedures, 1 CFU 100 ml<sup>-1</sup> NB was incubated for 18 h at 37°C without shaking. In this way, the cells reached stationary phase in an essentially anaerobic environment [19]. This approach enables the cells to grow by fermentative metabolism, in contrast to aerobic shake cultures, which would grow by respiratory metabolism. Using cells grown under fermentative conditions enables the effects of oxygen sensitivity to be studied in the experiments, since such cells are likely to show heightened responses to oxygen. The pH of the nutrient broth was adjusted to be slightly alkaline (pH 7.5) using 0.01 mol L<sup>-1</sup> HEPES/NaOH [4-(2-Hydroxyethyl)-1-piperazine ethanesulfonic acid, HiMedia, Mumbai, India] for *V. cholerae*. The culture was then centrifuged at 5300 × g for 5 min at 5°C and rinsed twice with 0.85% NaCl to remove all traces of growth medium. The pellet was then suspended in the same volume of sterile distilled water and then diluted to 1:100 for experimental purposes, i.e. 100 ml of bacterial suspension was added to 10 litres of sterile distilled water at pH 7.0 for *S. Typhi*, *S. Typhimurium* and 7.5 for *V. cholerae* to give a to give a final density of 10<sup>6</sup> -10<sup>7</sup> colony forming units per millilitre (CFU mL<sup>-1</sup>) at 0 h.

### Water source and Storage vessel

Sterile distilled water was used for all experimental procedures. This water was adjusted to pH 7.0 for *S. Typhi* and *S. Typhimurium* and to pH 7.5 for *V. cholerae*. Copper vessels (12 litre capacity), obtained from the local market in Chandigarh were disinfected, scrubbed and rinsed thoroughly to remove any adherent contamination from the inner surface. In order to mimic the rural setting in a laboratory by keeping the cleansing and disinfecting step simple, easy and cost-effective, the present method of rinsing with water, disinfecting and rinsing thoroughly three times with several litres of sterile distilled water each time before use was carried out [20]. Chemical analysis of the composition of the copper vessels was carried out using the Test-Master Pro, WAS Worldwide Analytical Systems AG, Wellesweg, Germany

and was found to contain 95% copper and 4.59% zinc. The mouths of all vessels were kept covered with sterile paper during the test procedure, to prevent airborne contamination of the water stored within. No contaminant colonies were seen during experimentation, confirming the effectiveness of this approach.

### Laboratory experiments

Suspensions of each bacterial strain were stored in water in copper vessels at 30°C for 24 h. Samples were withdrawn at 0, 2, 4, 6, 8, 10, 12 and 24 h, and serial decimal dilutions were prepared for each sample, to cover the dilution range  $10^0$ - $10^{-4}$ . Triplicate nutrient agar plates with and without 0.05% w/v sodium pyruvate, peroxide quencher [19,21], were prepared for each sample/dilution using a modified Miles and Misra surface droplet method [11], where 20  $\mu$ l of each dilution was placed onto the surface of pre-dried agar medium within a petri plate using a calibrated micropipette. The droplets were then spread across the surface of the medium using an inoculation loop, with 3 droplets per plate. Each drop is of 20  $\mu$ l volume, making it 60  $\mu$ l when the results for triplicate drops are added together. Here the loop was simply used to spread out the whole droplet, as an alternative to a 'spreader' (due to the smaller size of the droplet). Suspensions of each bacterial strain were stored in glass vessels under identical conditions and were processed similarly for enumeration. Each experiment was repeated three times with each strain.

### Enumeration

Nutrient agar plates without 0.05% w/v sodium pyruvate were incubated in a conventional aerobic incubator at 37°C for 24 h while nutrient agar plates supplemented with 0.05% w/v sodium pyruvate were incubated anaerobically in an anaerobic jar (HiMedia System Mark II) at 37°C for 24 h (ROS-n conditions) followed by further 24 h incubation at 37°C under normal aerobic conditions to ensure that all colonies were large enough to count. A non-selective medium was able to be used as the experiments were carried out with a pure suspension of a single bacterium [no contaminants were present]. Colonies were counted following the appropriate incubation period and the data expressed as CFU  $\text{ml}^{-1}$  by correcting for dilution and volume. The minimum count (detection limit) in all the experiments was 1 colony forming unit (CFU) in 3  $\times$  0.02 ml aliquots (0.06 ml) which corresponds to 16.7 CFU  $\text{mL}^{-1}$  (colony forming unit =  $\{\text{C}/\text{V}\} \times \text{M}$ ) or 1.222 when expressed as a log value. This has been represented in all the graphs as a dotted horizontal trend line. At any given time point during the course of the experiment, if the counts were below 1 CFU per 0.06 ml, they were regarded as counts below the minimum detection limit (< 1.222). It is important to appreciate that such values

cannot be shown directly on a log scale: in experiments where the counts fell below the detection limit, the plotted curve appears to stop at the last recorded positive count but it is important to realise that this does not mean that samples were not taken and processed for time point beyond this value, but that the values cannot be shown, since they are < 1.222.

### Statistical analysis

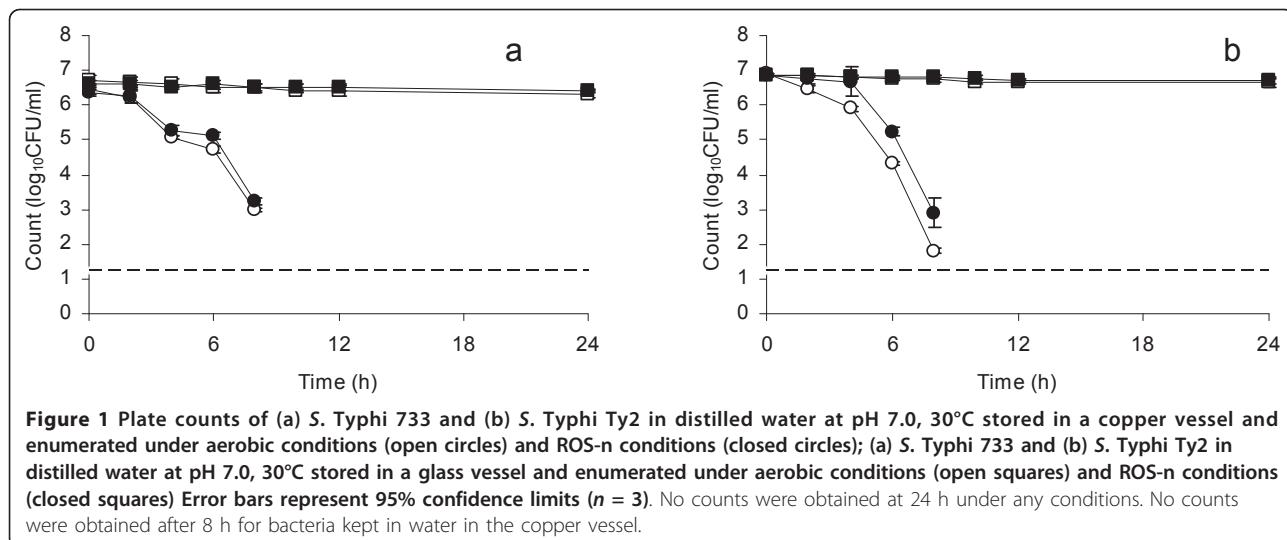

Colony counts are expressed as mean  $\log_{10}\text{CFU ml}^{-1}$  with 95% confidence limits. 95% confidence limits were used for error bars in the graphs. Differences between log-transformed means of conventional (aerobic) and ROS-n counts were statistically evaluated using *t* tests. The *t* and *p* value for two sets of log values at the same time point was calculated using the *t test: paired two sample for means* function in Microsoft Excel spreadsheet.

### Results

Figure 1a and 1b show the inactivation and sub-lethal injury of *S. Typhi* 733 and *S. Typhi* Ty2 in water stored in a copper vessel for up to 24 h, enumerated under normal aerobic conditions and ROS-n conditions. Counts for both strains fell below the minimum detection limit by 10 h with the degree of sub-lethal injury, demonstrated in terms of the difference between aerobic and ROS-n counts, being more pronounced for *S. Typhi* Ty2 at 48 h. This difference was statistically significant at 4 h (*t* = 8.21, *p* = 0.01) and beyond. A statistically significant difference between aerobic and ROS-n counts of *S. Typhi* 733 was also observed at 4 h (*t* = 5.26, *p* = 0.03). No counts were detected for both strains after 8 h under aerobic conditions and ROS-n conditions.

*S. Typhimurium* 98 and *S. Typhimurium* 1251 (Figure 2a and 2b) were less rapidly inactivated than the strains of *S. Typhi*, with counts at 12 h but not at 24 h. A significant difference was observed between aerobic and ROS-n counts at 12 h (*t* = 15.55, *p* = 0.004 for *S. Typhimurium* 98 and *t* = 23.93, *p* = 0.002 for *S. Typhimurium* 1251), indicating sub-lethal injury to both strains. Counts for both strains of *S. Typhimurium* fell below the minimum detection limit after 12 h under aerobic and ROS-n conditions.

For *V. cholerae* 3906 and *V. cholerae* O1 there was minimal change in counts over the first 4 h of storage, followed by a more rapid decrease with both aerobic and ROS-n counts falling below minimum detection limit after 10 h (Figure 3a and 3b). Compared to *S. Typhi* and *S. Typhimurium*, the two test strains of *V. cholerae* demonstrated the largest difference between aerobic and ROS-n counts at 10 h (*t* = 60.48, *p* = 0.0003 for *V. cholerae* 3906 and *t* = 4.0.20, *p* = 0.0006 for *V. cholerae* O1). Such differences represent a substantial number of sub-lethally injured cells, e.g. at 10 h the

**Figure 1** Plate counts of (a) *S. Typhi* 733 and (b) *S. Typhi* Ty2 in distilled water at pH 7.0, 30°C stored in a copper vessel and enumerated under aerobic conditions (open circles) and ROS-n conditions (closed circles); (a) *S. Typhi* 733 and (b) *S. Typhi* Ty2 in distilled water at pH 7.0, 30°C stored in a glass vessel and enumerated under aerobic conditions (open squares) and ROS-n conditions (closed squares). Error bars represent 95% confidence limits ( $n = 3$ ). No counts were obtained at 24 h under any conditions. No counts were obtained after 8 h for bacteria kept in water in the copper vessel.

counts were  $5 \times 10^2$  CFU ml<sup>-1</sup> for *V. cholerae* 3906 under aerobic conditions and  $1.5 \times 10^4$  CFU ml<sup>-1</sup> under ROS-n conditions, with equivalent counts for *V. cholerae* O1 of  $5 \times 10^2$  CFU ml<sup>-1</sup> and  $1.0 \times 10^4$  CFU ml<sup>-1</sup>.

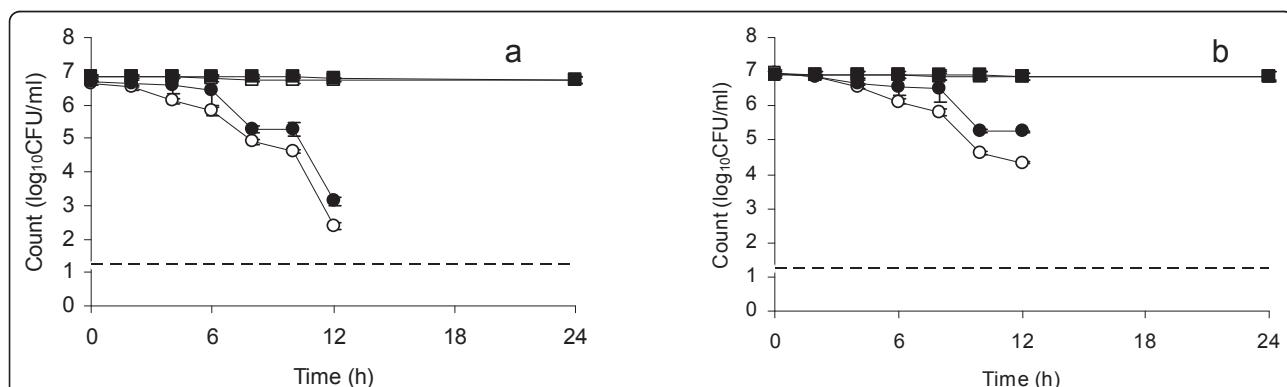

Overall, all test strains were completely inactivated (with no counts obtained under aerobic or ROS-n conditions) by storage in water kept in a copper vessel for 24 h, though all demonstrated sub-lethal injury (sensitivity to aerobic enumeration conditions) during shorter-term exposure. In contrast, storage of the same strains in water maintained in glass vessels resulted in no substantial change in aerobic or ROS-n counts up to 24 h (control data shown in Figures 1, 2, 3).

## Discussion

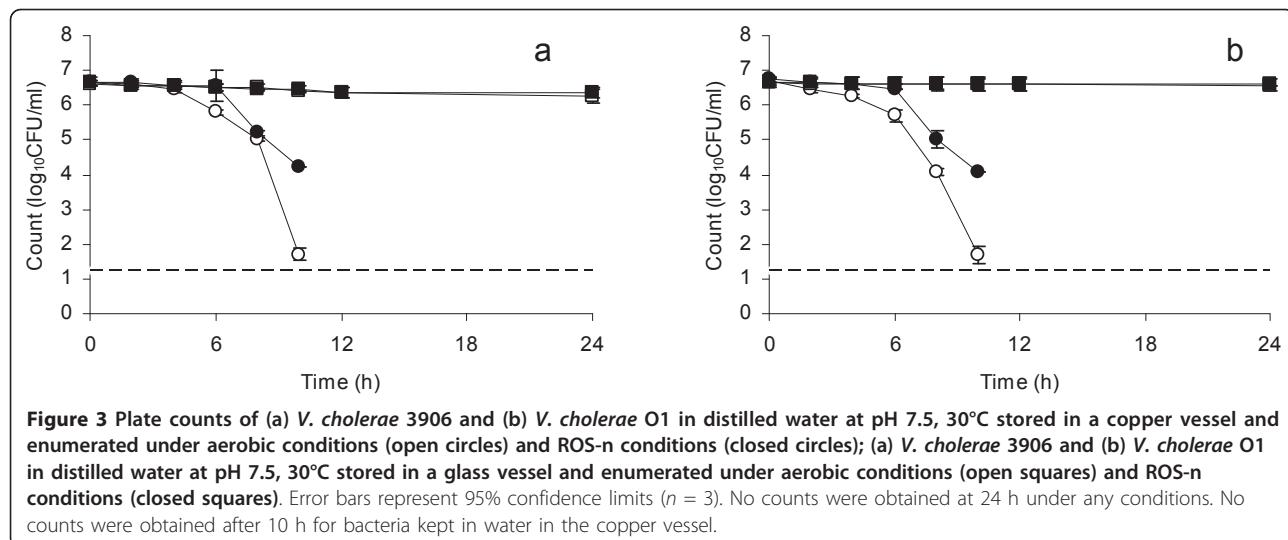

Despite global initiatives in water and sanitation, enteric fever and cholera remain major public health problems in

many developing countries [22,23], primarily due to lack of adequate sanitation facilities and safe drinking water, alongside issues related to personal hygiene [24]. Not only are some sources of drinking water contaminated, the likelihood of post-collection contamination during transport and/or storage at the household level is also high [25]. Given the large population of developing nations such as India and the scarcity of water resources, there is an unmet need to address the issue of point-of-use disinfection of drinking water, especially in rural settings. One of the proposed solutions to this problem was installation of boreholes and community wells. However, these protected sources of water are usually located far away from homes and require storage for some time before consumption [26], leaving the problem of post-collection contamination.

The present study has established the antibacterial effect of copper against some of the most important

**Figure 2** Plate counts of (a) *S. Typhimurium* 98 and (b) *S. Typhimurium* 1251 in distilled water at pH 7.0, 30°C stored in a copper vessel and enumerated under aerobic conditions (open circles) and ROS-n conditions (closed circles); (a) *S. Typhimurium* 98 and (b) *S. Typhimurium* 1251 in distilled water at pH 7.0, 30°C stored in a glass vessel and enumerated under aerobic conditions (open squares) and ROS-n conditions (closed squares). Error bars represent 95% confidence limits ( $n = 3$ ). No counts were obtained at 24 h under any conditions. No counts were obtained after 12 h for bacteria kept in water in the copper vessel.

water-borne pathogens of developing nations, namely *S. Typhi*, *S. Typhimurium* and *V. cholerae*. We have also demonstrated that injury is caused to the bacteria during short-term storage, and that this must be taken into account in order to obtain a comprehensive view of the antibacterial process, since ROS-sensitive bacteria are not detected by conventional procedures, and would therefore be missed during counting using standard laboratory methods and media. This is a significant finding as the sub-lethally injured microorganisms maybe as important as their healthy counterparts as they could have the potential to resuscitate in a favourable environment [27]. The frequency of isolation of *V. cholerae* and *V. vulnificus* is affected by environmental conditions [28] and it has been proposed that such organisms may enter a viable-but-non-culturable (VNC) state [29]. However, such an interpretation is typically based on conventional aerobic counts, and the ROS sensitivity of sub-lethally injured cells of *V. vulnificus* [30] provides an alternative possibility. Thus the resuscitation of starved *V. vulnificus* [31] and *V. parahaemolyticus* [32] through supplementation of the growth medium with pyruvate- and/or catalase reinforces the need to consider ROS-n conditions for bacterial enumeration.

The findings of the present study are significant at the practical level, since they provide information that extends the findings of earlier studies, based on conventional aerobic counts [14,15]. While there is a possibility that cells of pathogenic bacteria may not be completely inactivated when water is stored for short-term periods in copper vessels, our results clearly demonstrate that 24 h is sufficient to reduce counts of all tested strains of *S. Typhi*, *S. Typhimurium* and *V. cholerae* by  $> 10^5$  CFU ml<sup>-1</sup>, dropping below the minimum detection limit by this time. Consequently, 24 h storage is recommended in preference to

shorter-term storage, e.g. overnight. Our previous studies have demonstrated leaching of copper ions when water is stored at 35°C at pH 7.0. The total dissolved copper was measured using a Perkin-Elmer Analyst atomic absorption spectrophotometer, Perkin-Elmer, USA at the Post Graduate Institute of Medical Sciences, Chandigarh [33]. Clearly, the inactivation is not due to nutritional stress, as in a glass vessel there is no lethality. The levels of copper in the vessel are not sufficient to be of concern in any nutritional or osmotic sense - they are still low, but enough to injure and then inactivate the bacteria.

## Conclusions

Effective point-of-use water disinfection methods are required to reduce the incidence of diarrhoeal diseases in developing nations such as India. We have demonstrated the value of using traditional copper storage vessels to inactivate the water-borne pathogens responsible for typhoid fever and cholera, while also highlighting the occurrence of sub-lethal injury during storage for periods of less than 24 h. The application of improved methods for water storage at the household level are likely to have a significant impact on the overall health of the community [25,26].
