Uncovering fungal community composition in natural habitat of *Ophiocordyceps sinensis* using high-throughput sequencing and culture-dependent approaches

Chuan-Bo Zhang^{*}, Chao-Hui Ren, Yan-Li Wang, Qi-Qi Wang, Yun-Sheng Wang and Qing-Bei Weng

Abstract

Background: The fungal communities inhabiting natural *Ophiocordyceps sinensis* play critical ecological roles in alpine meadow ecosystem, contribute to infect host insect, influence the occurrence of *O. sinensis*, and are repertoire of potential novel metabolites discovery. However, a comprehensive understanding of fungal communities of *O. sinensis* remain elusive. Therefore, the present study aimed to unravel fungal communities of natural *O. sinensis* using combination of high-throughput sequencing and culture-dependent approaches.

Results: A total of 280,519 high-quality sequences, belonging to 5 fungal phyla, 15 classes, 41 orders, 79 families, 112 genera, and 352 putative operational taxonomic units (OTUs) were obtained from natural *O. sinensis* using high-throughput sequencing. Among of which, 43 genera were identified in external mycelial cortices, *Ophiocordyceps*, *Sebacinia* and *Archaeorhizomyces* were predominant genera with the abundance of 95.86, 1.14, 0.85%, respectively. A total of 66 genera were identified from soil microhabitat, *Inocybe*, *Archaeorhizomyces*, unclassified *Thelephoraceae*, *Tomentella*, *Thelephora*, *Sebacina*, unclassified *Ascomycota* and unclassified fungi were predominant genera with an average abundance of 53.32, 8.69, 8.12, 8.12, 7.21, 4.6, 3.08 and 3.05%, respectively. The fungal communities in external mycelial cortices were significantly distinct from soil microhabitat. Meanwhile, seven types of culture media were used to isolate culturable fungi at 16 °C, resulted in 77 fungal strains identified by rDNA ITS sequence analysis, belonging to 33 genera, including *Ophiocordyceps*, *Trichoderma*, *Cytospora*, *Truncatella*, *Dactylonectria*, *Isaria*, *Cephalosporium*, *Fusarium*, *Cosmospora* and *Paecilomyces*, etc.. Among all culturable fungi, *Mortierella* and *Trichoderma* were predominant genera.

Conclusions: The significantly differences and overlap in fungal community structure between two approaches highlight that the integration of high-throughput sequencing and culture-dependent approaches would generate more information. Our result reveal a comprehensive understanding of fungal community structure of natural *O. sinensis*, provide new insight into *O. sinensis* associated fungi, and support that microbiota of natural *O. sinensis* is an untapped source for novel bioactive metabolites discovery.

Background

The caterpillar fungus *Ophiocordyceps sinensis* parasitizes the larvae of *Thitarodes* that belongs to family Hepialidae (Lepidoptera) form the fungus-caterpillar complex (Chinese *Cordyceps*) [1]. *O. sinensis* mainly inhabits the alpine meadow ecosystem of Qinghai–Tibetan Plateau, Sichuan, Yunnan and Gansu Provinces in China, also distributes in certain areas of Bhutan, Nepal and India [2]. As the well-known traditional Chinese medicinal herb, *O. sinensis* has been widely used for centuries in Asia, exhibit beneficial properties and remedy for a variety of chronic disorders, including asthma, cancer, sexual dysfunction, obesity, type 2 diabetes and fatigue, etc., presumably, by modulating the composition of gut microbiota [3–6]. *O. sinensis* harbour a variety of bioactive metabolites, e.g., cordycepin, cordycepic acid, polysaccharides, ergosterol, mannitol and macrolides, etc.. It may be considered as key factors in the coevolution of *O. sinensis* and its host, coevolution of symbiotic and associated microbiota. The huge world market demand and price of *O. sinensis* continue to increase because of its pharmacological application, obligate parasitism and special dependence on ecological environments, which led to overexploitation, severely endangering numerous natural populations of *O. sinensis* towards its extinction and damage of its habitats. Artificial cultivation of *O. sinensis* has been successful, but commercial cultivation is difficult to perform because the cryptic factors triggering the development and maturation of *O. sinensis* remains obscure [7]. Currently, the soil originated from habitats of natural *O. sinensis* is indispensable in later stages of artificial cultivation. Therefore, illuminating mysterious drive factor in the occurrence and maturation of *O. sinensis*, enhancing the yield and discovery of its alternative substitutes, have already become hot topics.

Generally, *O. sinensis* is exclusively endemic to alpine meadow ecosystem of the Qinghai-Tibetan Plateau and its adjacent high-altitude area in China, which is characterized by low soil temperature, fragile plant community structure and extremely sensitive to climate change. Natural *O. sinensis* and its surrounding soil construct a microecosystem, which represent the reservoir of microbial species. Uncovering the fungal community structure of natural *O. sinensis* are significant in understanding the occurrence of *O. sinensis* and artificial cultivation. Recently, a wide variety of fungal species have been discovered from natural *O. sinensis* using culture-dependent approach, including *O. sinensis*, *Chrysosporium sinense*, *Paecilomyces hepiali*, *Tolypocladium sinense* and *Paecilomyces sinensis*, etc., all of which are excellent potential sources of novel bioactive metabolites for drug discovery [8, 9]. Except the caterpillar fungus *O. sinensis*, all the others are symbiotic or associated fungi [10, 11].

Molecular evidence demonstrates the existence of both *O. sinensis* and *P. hepiali* DNA in the caterpillars and fruiting bodies of *O. sinensis*.

Recently, *O. sinensis* is confronted with reduction of output and geographical distribution shrink, which might result from microbial community disturbance in habitat environment by over-exploitation, global warming, heavy grazing and habitat deterioration, etc. [12]. Significantly, a variety of fungal species isolated from natural *O. sinensis* were applied in clinical treatment because of its health benefits. More than 200 novel bioactive metabolites have been isolated from these associated fungi (referred to as *Cordyceps*-colonizing fungi) [13, 14]. Particularly, the mycelia of *P. hepiali* obtained by solid state fermentation or submerged liquid fermentation produce a large repertoire of bioactive metabolite similar to natural *O. sinensis*, also exhibit beneficial properties, including antioxidant, anti-fatigue, anti-aging, anti-diabetic, anti-inflammatory and anti-depressant-like effects [15, 16]. Currently, *P. hepiali* has been widely used as an alternative to natural *O. sinensis*, because of its high productivity and similar health effects. These different fungal species produce similar bioactive metabolites, presumably, due to horizontal transfer of secondary metabolic biosynthetic gene cluster in microbiota of natural *O. sinensis*. Meanwhile, more fungal species originating from natural *O. sinensis* need to be discovered for developing alternative products, and applied in clinical practice.

Natural *O. sinensis* associated microbiota play vital roles in nutrient cycling, establishment of infection cycle of insect hosts, growth and maturation of sclerotia and fruiting body (stroma). Within the last decade, progressive studies have been devoted to isolate and identify fungal species from habitats of *O. sinensis* by culture-dependent approach. A total of 572 isolates have been obtained from different parts of *O. sinensis* (fruiting body, sclerotia and external mycelial cortices) at 25 °C, belonging to 37 fungal genera, Ascomycota, Basidiomycota and Zygomycota were the predominant fungal phyla, which have provided fundamental insights into fungal community of native *O. sinensis* on the Qinghai-Tibetan Plateau [8]. However, only a small fraction of microbial community were culturable using traditional culture dependent approach [17, 18]. Previously, 490 fungal clones were identified from the whole-community DNA using PCR-single-strand conformation polymorphism (PCR-SSCP) method, 266 of these clones were selected for sequencing and assigned to 21 genera [9]. Three main phyla, including Ascomycota, Basidiomycota, Zygomycota and a notable numbers of unclassified fungi, especially, in the sclerotia and external mycelial cortices were detected by high-throughput 454 sequencing technology [19].

Currently, Illumina Miseq high-throughput sequencing has been the most promising approach to explore microbial community composition and dynamic across special habitat, agriculture, traditional solid-state fermentation, deep-sea sediments and Chinese liquor starter, etc., due to its cost-effective, more sequences per sample, especially the capability of less abundant species mining [20–25]. However, the data obtained from samples by this approach were determined by the quality of microbial DNA extracted from samples, PCR amplification efficiency, quality of 16S rRNA or ITS regions library and other uncertain factors, which easily lead to offset or error of microbial diversity. In addition, due to short length of Miseq sequencing, the OTUs could be identified to the genus level.

Recently, *O. sinensis* associated fungi are increasingly attracting the attention as potential health benefits agent. The relationship between *O. sinensis* and its microbiota also represents one of the most evolutionarily ancient examples of symbiosis in ecosystem. The microbial community of unfertilized eggs from *Thitarodes* were analyzed via 16S rRNA and ITS sequencing, revealed that 348 bacterial genera belong to 26 phyla, and 289 fungal genera, mainly including *Aureobasidium*, *Candida* and *Cryptococcus*, etc., belonging to 5 phyla, namely, Ascomycota, Basidiomycota, Chytridiomycota, Glomeromycota and Zygomycota [26]. However, microbial communities of natural *O. sinensis*, ecological functions and metabolic potential remain largely unexplored. Here, the present study aimed to comprehensively uncover fungal communities in external mycelial cortices and soil microhabitat. The samples derived from different sites distributed across Golog Tibetan Autonomous Prefecture of Qinghai-Tibetan Plateau, were investigated using high-throughput sequencing and various types of culture media. These results would provide a comprehensive understanding of complex microbial ecosystem around natural *O. sinensis*, be beneficial to overcome the obstacle in artificial culture of *O. sinensis*.

Results

Quality analysis of sequencing data

A total of 280,519 high quality fungal sequences were generated from six samples (external mycelial cortices: JM-1, JM-2, JM-3, soil microhabitat: TY-2, TY-3, TY-4) using Illumina Miseq sequencing. Each sample provided more than 32,568 fungal ITS sequences with an average length of 280.54 bp. The high quality sequence length of the samples from soil microhabitat is 200 ~ 340 bp, the average length is 307.02 bp. The high quality sequence length of the samples from external mycelial cortices is 240 ~ 260 bp, and the average length is 254.06 bp, which is consistent with the prediction based on the primer site (Table 1).

Table 1 Quality analysis of sequences from different samples

Sample	Sequences	Bases (bp)	Average Length (bp)
TY2	32,568	10,530,892	323.35
TY 3	37,531	11,194,578	298.28
TY 4	87,493	16,197,280	299.42
JM 1	35,546	9,036,787	254.23
JM 2	42,817	10,862,727	253.70
JM 3	44,564	11,330,766	254.25

Richness and diversity of fungal community in natural *O. sinensis*

In all six samples derived from external mycelial cortices and soil microhabitat, the coverage values close to 100%, and the rarefaction curves were asymptotic, indicating that overwhelming majority of the fungal species were covered (Fig. 1). The total number of ITS reads obtained from all six samples, after filtering chimeric sequences and mismatches, were clustered into 352 OTUs with at 97% similarity in nucleotide identity. One hundred and seventy OTUs were derived from the external mycelial cortices, 291 OTUs were derived from the soil microhabitat, and 109 OTUs were shared.

To better understand the differences among the microbial communities, it is important to calculate the richness and diversity. The species richness of fungal communities can be demonstrated by Chao1 index and ACE index. Simpson index and Shannon index were used to analyze the diversity of fungal community, which demonstrate not only the species richness but the evenness of the species. In natural *O. sinensis*, the patterns of Chao1 and ACE are very similar to the OTUs numbers, the Chao1 and ACE indices from external mycelial cortices are 102.9 ± 23.0 , 105.1 ± 21.9 , respectively, the Chao1 and ACE indices from soil microhabitat are 241.4 ± 56.0 , 248.9 ± 50.4 , respectively, which indicate that the external mycelial cortices had lower species richness of the fungal community than soil microhabitat (Table 2). The Shannon and Simpson index of the external mycelial cortices were 0.28, 0.9166, the soil samples were 1.89, 0.3367, respectively. The Shannon index of external mycelial cortices was lower than soil microhabitat, in contrast, the Simpson index of external mycelial cortices was higher than soil microhabitat. The results indicate that taxonomic diversity of the fungal community in soil microhabitat are higher than external mycelial cortices.

Fungal community structure analysis of *O. sinensis* using high-throughput sequencing

The fungal community structure of *O. sinensis* were evaluated at the phylum, class and genus levels. All high-quality sequences generated from external mycelial cortices and soil microhabitat belong to 5 fungal phyla, 15

Fig. 1 Rarefaction curves of OTUs clustered at < 97% sequence identity for the six samples

Classes, 41 orders, 79 families, 112 genera, 352 OTUs. A total of 4 fungal phyla were identified in external mycelial cortices samples, including Ascomycota, Basidiomycota, Zygomycota and unclassified fungi, the average abundance were 98.02, 1.79, 0.07, 0.12%, respectively. Ascomycota was the predominant fungus in external mycelial cortices samples of natural *O. sinensis*. A total of 5 fungal phyla were identified in soil microhabitat samples, including Basidiomycota, Ascomycota, Zygomycota, Glomeromycota and unclassified fungi, the abundance were 82.66, 14.06, 0.18, 0.05 and 3.05%, respectively (Fig. 2a). Significantly, Basidiomycota and Ascomycotawas were the predominant fungi in soil microhabitat, and Glomeromycota was not detected in external mycelial cortices. The proportions of Ascomycota in the external mycelial cortices of *O. sinensis* were significantly higher than soil microhabitat.

The composition of fungal community were further analyzed at the genus level. Among 5 fungal phyla, a total of 112 genera were identified across all investigated samples. In total, 43 genera were discovered in external mycelial cortices, *Ophiocordyceps*, *Sebacina* and *Archaeorhizomyces* were predominant genera accounted for 95.86, 1.14, 0.85%, and the genus *Ophiocordyceps* was overwhelmingly

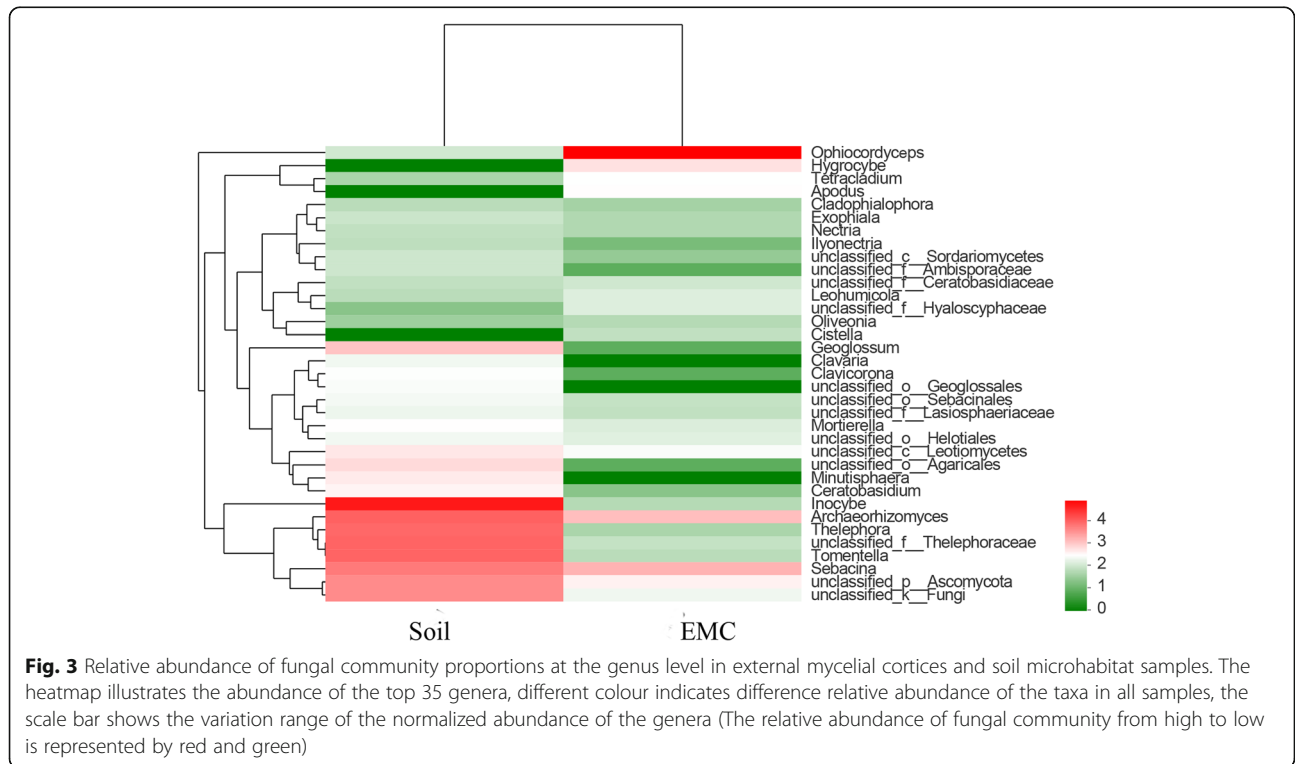

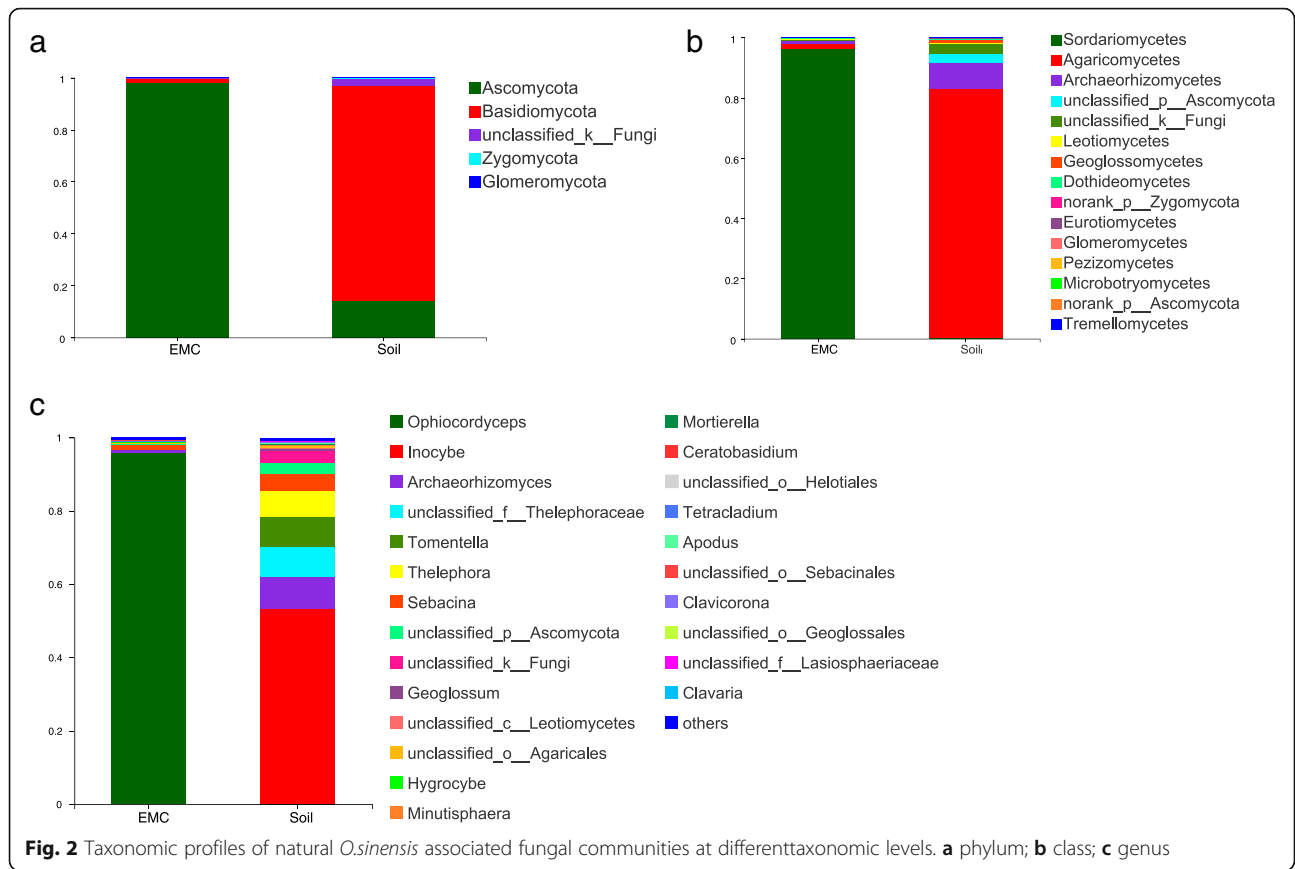

dominant in external mycelial cortices. A total of 66 genera were discovered in soil microhabitat, *Inocybe*, *Archaeorhizomyces*, unclassified *Thelephoraceae*, *Tomentella*, *Thelephora*, *Sebacina*, unclassified *Ascomycota*, unclassified fungi were dominant genera with an average abundance of 53.32, 8.69, 8.12, 8.12, 7.21, 4.6, 3.08 and 3.05%, respectively. In total, 34 genera were shared, among of which, *Sebacina*, *Archaeorhizomyces*, *Apodus*, *Tetracladium*, *Mortierella* and *Cistella* had higher abundance in external mycelial cortices, accounted with 1.14, 0.85, 0.18, 0.17, 0.07, 0.04%, respectively. However, *Inocybe*, *Archaeorhizomyces*, *Tomentella*, *Thelephora*, *Sebacina* and *Geoglossum* had higher abundance in soil microhabitat, accounted with 53.32, 8.69, 8.12, 7.21, 4.61, 0.74%, respectively. The average abundance of other genera are lower than 0.01%.

In addition, a total of 9 genera, namely, *Botrytis*, *Cladosporium*, *Coniochaeta*, *Hygrocybe*, *Lachnum*, *Laetisaria*, *Leucosporidiella*, *Ophiocordyceps* and *Trichoderma* were unique to external mycelial cortices. A total of 32 genera were unique to soil microhabitat samples, *Acremonium*, *Alternaria*, *Ambispora*, *Aspergillus*, *Basidiobolus*, *Cercophora*, *Clavaria*, *Clavulinopsis*, *Cotylidia*, *Cryptococcus*, *Elaphomyces*, *Elasticomyces*, *Entoloma*, *Glarea*,

Table 2 Richness and diversity of the fungal community from samples at 97% similarity

Sample	OTU	ACE index	Chao1 index	Shannon index	Simpson index
Soil	291	248.9 ± 50.4 ^a	241.4 ± 56.0 ^a	1.89 ± 0.55 ^a	0.3367 ± 0.2104 ^a
EMC	170	105.1 ± 21.9 ^b	102.9 ± 23.0 ^b	0.28 ± 0.14 ^b	0.9166 ± 0.0450 ^b

Values are means ± standard deviation, different letters (a,b) indicate significantly different ($p < 0.05$)

Gloiocephala, *Humicola*, *Hymenula*, *Lecythophora*, *Leptosphaeria*, *Minutisphaera*, *Monographella*, *Mrakia*, *Mycena*, *Neopeckia*, *Ophiosphaerella*, *Penicillium*, *Pluteus*, *Porothelium*, *Rhodotorula*, *Russula*, *Scutellinia* and *Tarzetta*. Among of which, *Minutisphaera* and *Scutellinia* have higher abundance of 0.29, 0.02%, respectively, the others with an average abundance less than 0.01% (Fig. 2c).

Comparison of fungal communities from different samples in natural *O. sinensis*

Heatmap were performed based on the abundance information of each one from top 35 genera in different samples, which can visually reveal that the fungal communities in the external mycelial cortices of natural *O. sinensis* were significantly different from soil microhabitat samples (Fig. 3). The UniFrac-weighted Principal Coordinate Analysis (PCoA) showed that JM-1, JM-2, JM-3 were clustered together, TY-2, TY-3, TY-4 were separated on other side, which revealed that there are significant differences in fungal community structure between external mycelial cortices and soil microhabitat (Fig. 4). Dispersed state was observed among the samples from soil microhabitat collected from different sites, which indicating that the fungal communities composition were highly varied significantly in soil microhabitat across different areas. Venn diagram analysis revealed that 61 OTUs were exclusive to external mycelial cortices, 182 OTUs were exclusive to soil microhabitat, and

109 OTUs were shared (Fig. 5). Comparative analysis at the OTU level reveal that caterpillar fungus *O. sinensis* was overwhelmingly dominant in the external mycelial cortices, with proportion of 95.85%. Other predominant fungal species including *Archaeorhizomyces* sp., *Sebacina dimitica*, unclassified Ascomycota, accounted with 0.85, 0.86, 0.24%, respectively. However, unclassified *Inocybe*, *Archaeorhizomyces* sp., unclassified *Thelephoraceae*, unclassified *Tomentella*, *Thelephora* sp., unclassified Ascomycota, unclassified fungi, *Sebacina dimitica* and unclassified *Sebacina* were predominant fungal species in soil microhabitat, with proportion of 53.03, 8.69, 8.12, 8.09, 7.21, 3.08%, 3.05, 2.63, 1.57%, respectively (Fig. 6).

Diversity of cultivable fungi

The surface sterilization effect meet the requirements of this study. Culture-dependent approach provide better taxonomic resolution than high-throughput sequencing. The fungal isolates varied with the different types of media, a total of 77 fungi were isolated from external mycelial cortices and soil microhabitat using culture-dependent approach. Firstly, fungal isolates were classified according to the characteristics of the colonies. The representative fungal isolates were identified by ITS region of the rDNA gene. All sequenced fungal isolates belong to 2 fungal phyla, 4 Classes, 9 orders, 21 families, 33 genera, Ascomycota and Zygomycota were predominant fungi, with proportion of 77.33, 22.67%, respectively. A total of 33 fungal genera, including *Ophiocordyceps*, *Trichoderma*,

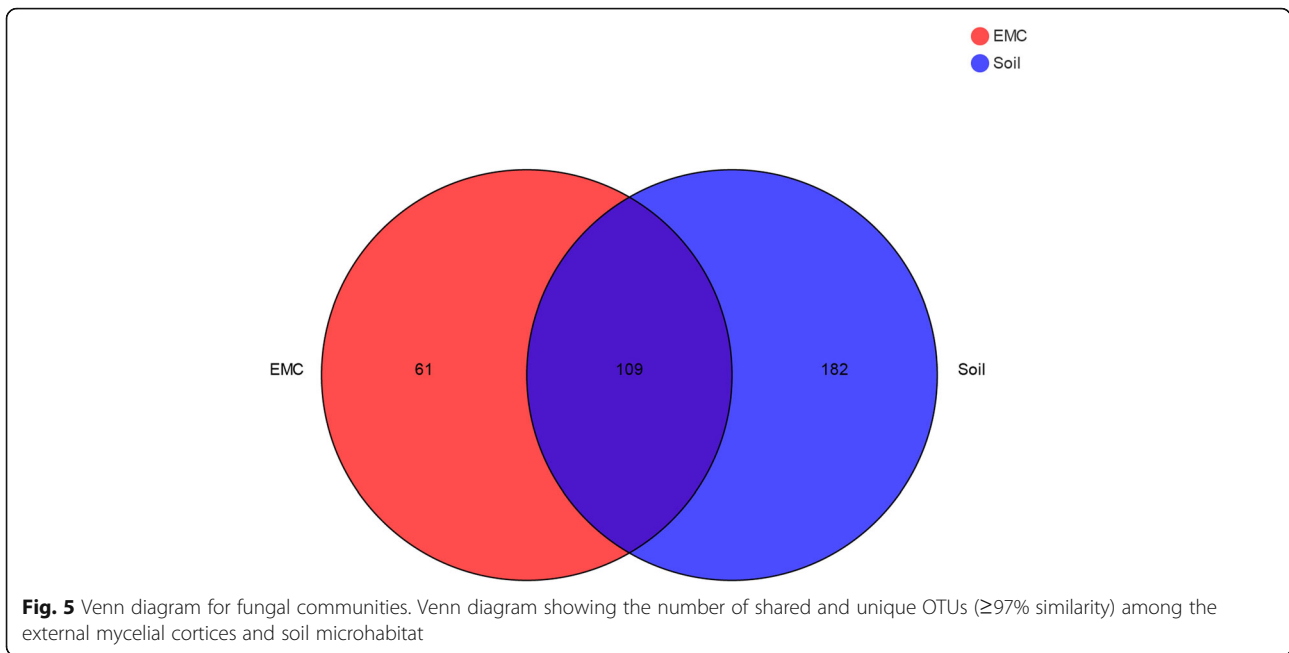

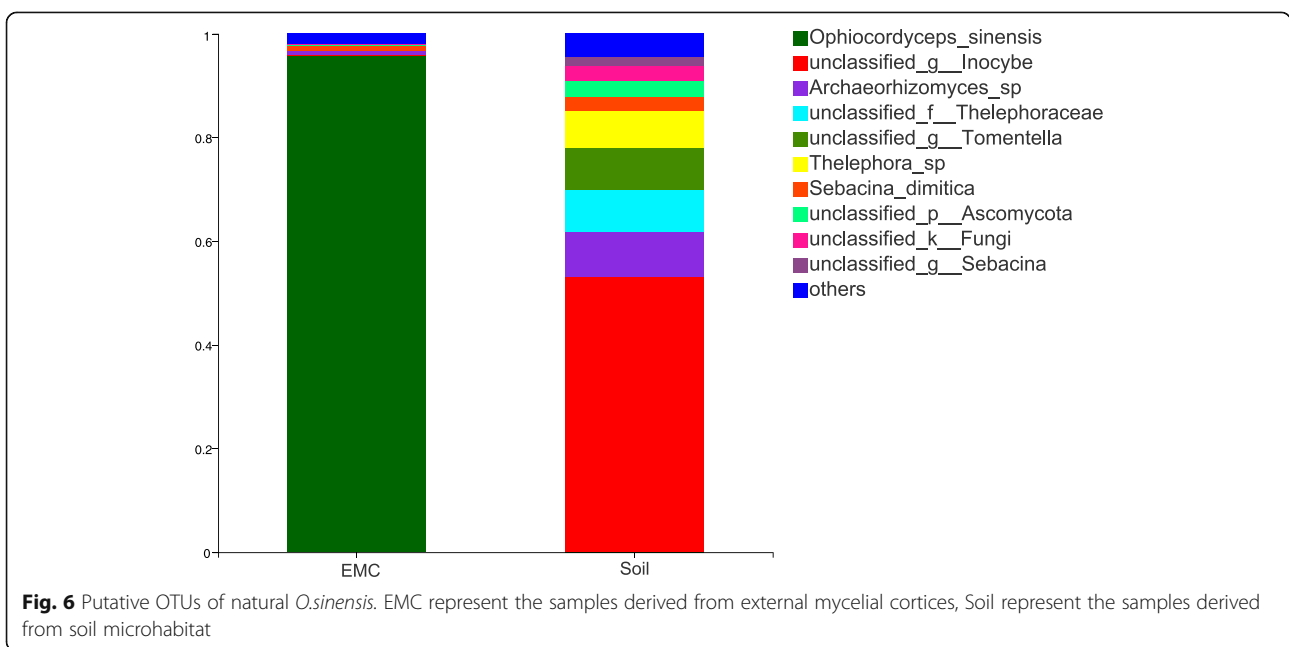

Fig. 4 Principal coordinates analysis of fungal communities in samples of external mycelial cortices and soil microhabitat. The OTU matrix used in the analyses was clustered at the 97% similarity and the principal coordinate's analysis was based on Weighted UniFrac distances. Cytospora, *Truncatella*, *Dactylonectria*, *Isaria*, *Cephalosporium*, *Fusarium*, *Cosmospora*, *Paecilomyces*, *Tolypocladium*, *Cercophora*, *Beauveria*, *Neonectria*, *Microdochium*, *Coniochaeta*, *Lecanicillium*, *Ilyonectria*, *Stagonosporopsis*, *Cladosporium*, *Pleotrichocladium*, *Leptosphaeria*, *Chaetosphaeronema*, *Paraphaeosphaeria*, *Preussia*, *Neosetophoma*, *Leptodontidium*, *Chalara*, *Pseudogymnoascus*, *Geomyces*, *Tetracladium*, *Mucor* and *Mortierella*, among of which, the predominant ones were *Mortierella* and *Trichoderma* (Table 3).

Comparison of culture-dependent and-independent approaches

Surprisingly, there are significant differences in fungal communities of external mycelial cortices and soil microhabitat between two approaches. In external mycelial cortices, many ectomycorrhizal fungi, Orchidaceae and lichen symbiotic fungi were discovered by high-throughput sequencing, including, *Tetracladium maxilliforme*, *Pyrenomataceae* sp., unclassified *Xylariales*, *Rachicladosporium antarcticum*, *Sebacinaceae*, unclassified *Sebacinales* and

Fusidium griseum, etc.. However, several entomopathogenic fungi and *Trichoderma* sp. fungi were isolated using culture-dependent approach, including *Tolypocladium cylindrosporum*, *Beauveria bassiana*, *Lecanicillium* sp., *Paecilomyces farinosus*, *Trichoderma paraviridescens* and *Trichoderma viridescens*, etc.. In soil microhabitat, many cold adapted yeast, lichen symbiotic fungi, endophyte fungi and phytopathogenic fungi were discovered by high-throughput sequencing, including, *Cryptococcus terricola*, *Cryptococcus victoriae*, *Elasticomyces elasticus*, *Rhodotorula lamellibrachiae* and *Alatospora* sp., etc.. Using culture-dependent approach, we isolated many fungal species from soil microhabitat, which belong to *Mortierella* sp., entomopathogenic fungi and endophyte fungi, e.g., *Mortierella minutissima*, *Isaria farinosa*, *Isaria fumosorosea* and *Paraphaeosphaeria sporulosa*, etc..

Discussion

The caterpillar fungus *O. sinensis* infects larvae of its hosts by oral cavity, insect cuticles or spiracle. After entering the hemolymph of host insect, the fungus grows as a hyphal body and threadlike hyphae, and converts it into caterpillar-shaped sclerotium. In the following year, mid-April to early June, the fruiting body bud growing on the head of sclerotium, emerging above the soil surface and forming a stalked fruiting body. Finally, ascospores were erupted from the mature fruiting body of *O. sinensis*, scatter in top soils, gradually infiltrate deeper into the soil, begin a new infection cycle. The dynamic changes and diversity of *O. sinensis* associated fungi in soil regulate the relationship of fungus-larvae, influence the occurrence and geographical distribution of *O. sinensis* [27]. In Qinghai-Tibet Plateau, fungi community also are key components of the fragile ecosystems, perform critical ecological functions in biogeochemical cycles by decomposing organic matter and recycling nutrients. Uncovering fungi community composition of natural *O. sinensis* have great significance for better elucidating the interaction between microbiome and *O. sinensis*, the occurrence and morphological variation of *O. sinensis*. However, it still lacked comprehensive investigation because of limitation of single approach.

In present study, 5 fungal phyla, 112 genera, and 352 OTUs were identified using Illumina MiSeq sequencing, a total of 43 fungal genera were discovered in external mycelial cortices, *Ophiocordyceps*, *Sebacina* and *Archaeorhizomyces* were predominant genera accounted for 95.86, 1.14, 0.85%. A total of 66 fungal genera were discovered from soil microhabitat, *Inocybe*, *Archaeorhizomyces*, unclassified *Thelephoraceae*, *Tomentella*, *Thelephora*, *Sebacina*, unclassified *Ascomycota* and unclassified fungi were dominant genera with an average abundance of 53.32, 8.69, 8.12, 8.12, 7.21, 4.6, 3.08 and 3.05%, respectively. Previous study revealed that *Ophiocordyceps* was

overwhelmingly dominant in the fruiting bodies and external mycelial cortices of the Chinese *Cordyceps*, which is consistent with our data. However, in soil samples, *Ophiocordyceps*, *Verticillium*, *Pseudallescheria*, *Candida*, *Ilyonectria*, *Neonectria* and *Fusarium* were the dominant genera [19]. Another previous study based on HiSeq sequencing of ITS genes of soil samples derived from the site that had a high density of *Thitarodes* larvae and Chinese *Cordyceps* at Shergyla Mountain revealed that *Archaeorhizomyces*, *Hyphodiscus*, *Beutheromyces*, *Pezoloma*, *Venturia*, *Geogiossum*, *Clavulinopsis*, *Cotylidia*, *Rammannopsis*, *Peltigera* and *Cavana* had high relative abundance [28]. Previous studies are inconsistent with each other, and also differ from our results, presumably, due to geographical origin, sampling processing and limitations of high-throughput sequencing, etc., which indicated that the *O. sinensis* associated microbial communities needs further study. In present study, 33 genera were isolated and identified using culture-dependent approach with different types of media incubated at 16 °C, which mimic the true growth temperature of natural *O. sinensis*. *Mortierella* and *Trichoderma* were predominant culturable fungal genera. The data obtained from previous study showed that *Penicillium chrysogenum* is the predominant fungal species from fruiting body, and *Pseudogymnoascus roseus* is the dominant fungal species from sclerotia and external mycelial cortices using PDA incubated at 20 °C [8]. In our study, *Pseudogymnoascus* sp., was isolated from external mycelial cortices, but was not a predominant fungal species. There are significant differences in distinct studies, presumably, owing to different culture temperatures, media, sampling process and geographical origin, etc., which reflect the complexity of microbial communities from natural *O. sinensis*.

Compared with culture dependent approach which had limitations because of the selectivity of media and culture conditions, high-throughput sequencing was considered to provide better resolution of microbial community composition, but, it still showed biases. Each approach tend to capture different microbial community fractions, result in only a fraction of the taxa recovered did overlap, which also highlighting the complementarity of two approaches [29, 30]. Therefore, it is believed that the coordination of culture-dependent and independent approaches would provide promising avenue to illuminate microbial community assembly in natural *O. sinensis*. The idea was supported by our results obtained from two approaches. Using high-throughput sequencing, many ectomycorrhizal fungi, Orchidaceae and lichen symbiotic fungi were unexpectedly discovered in external mycelial cortices. Although rarefaction curves combined with the estimated coverage values indicated that overwhelming majority of fungal species were revealed

TY indicates the fungi isolated from soil microhabitat, JM indicates the fungi isolated from external mycelial cortices

from the natural *O. sinensis*. There were only 2 fungal species obtained from culture dependent approach were detected by high-throughput sequencing, i.e., *Tetracladium* sp. and *Lecythophora* sp.. Significantly, several entomopathogenic fungi and *Trichoderma* sp. were isolated frequently using culture-dependent approach.

Various environmental factors, including terrain, vegetation characteristics, altitude, climate change and anthropogenic disturbance, etc., strongly regulate soil properties, soil temperature and moisture, which alter the microclimate, then shape microbial communities

composition of soil microhabitat [31]. The alpine meadow ecosystem of the Qinghai-Tibetan Plateau that suitable for the occurrence of *O. sinensis*, are the most fragile and sensitive to environmental factors change. The dynamic alterations of microbial community in natural habitat *O. sinensis* response to seasonal temperature fluctuation, are also need further study. Furthermore, soil microbial communities strongly influence the yield and occurrence of natural *O. sinensis*, because of the infection of host *Thitarodes* larvae mainly occurs in soils [28]. The suitable habitat of *O. sinensis* and host insects

mainly contain *Polygonum viviparum*, *Polygonum macrophyllum* D.Don., *Polygonum sphaerostachyum* Meisn., *Polygonatum curvistylum* and *Rheum tibeticum* Maxim. ex Hook.f., etc. [32]. The data from high-throughput sequencing reveal that ectomycorrhizal fungi, Orchidaceae and lichen symbiotic fungi, plant pathogenic fungi, endophytic fungi and large number of novel fungal species were widespread in soil microhabitat of natural *O. sinensis*. The fungus *O. sinensis* occupy the vast majority of fungal community in external mycelial cortices, has a selective effect on symbiotic and associated microbial species, as there are still many plant endophytic fungi in microbial community.

Regarding entomopathogenic fungi in natural *O. sinensis*, *Tolypocladium cylindrosporum*, *Paecilomyces farinosus*, *Isaria farinosa*, *Isaria fumosorose*, *Lecanicillium* sp. and *Beauveria bassiana* were isolated using culture-dependent approach in our results. Previous study revealed that *Metarhizium*, *Pochonia*, *Simplicillium*, *Elaphocordyceps*, *Polycephalomyces*, *Purpureocillium* and *Tolypocladium* are present in the Chinese *Cordyceps* [28]. *Sebacina*, a mycorrhizal fungus frequently isolated from Orchidaceae and plant, promote growth, enhance stress resistance and seed germination, was in high abundance in external mycelial cortices [33]. *Archaeorhizomyces*, a widespread fungal class with a dominant presence in many soil environments, increase plant bioactive components, enhance stress resistance and inhibit the occurrence of plant diseases by different mechanisms, also was high relative abundance genus in external mycelial cortices. *Trichoderma* spp. are proposed as major plant growth-promoting fungi in soils, significantly alter the rhizosphere soil chemistry, regulate microbial communities and improve grassland biomass [34]. *Trichoderma* species were frequently isolated from external mycelial cortices by culture-dependent approach, and also have been identified by high-throughput sequencing. Accumulated evidence and our data support the hypothesis that the caterpillar fungus *O. sinensis* parasitize the larvae of *Thitarodes* to form larva shape sclerotia, produce diverse secondary metabolites or organic ingredients, which could alter soil characteristic surrounding *O. sinensis*, influence the microbial community composition, form a complex host-microbiota microecosystem. The total protein content, pharmacological effect and bioactive components of natural *O. sinensis* are much higher than artificially cultivated *O. sinensis*, which indicate that shaping symbiotic and associated microbial species are significantly important in the growth and development of *O. sinensis* and formation of perithecial fruiting bodies. Presumably, these associated fungi might be the real producer of certain pharmacologically bioactive components in natural *O. sinensis*. A case of Truffles (*Tuber* spp.), are well

known for their enticing aromas partially emitted by microbes colonizing truffle fruiting bodies, their associated microbes related to stimulation of the growth of Tuber mycelium, inhibition of pathogenic fungi, the elaboration of the complex aroma of truffles [35]. The data presented here highlight the importance of several fungi in *O. sinensis*, namely *Trichoderma* sp., *Archaeorhizomyces*, *Sebacina*, insect pathogenic fungi and mycorrhizal fungi, etc., the synergistic effect of different fungi help to produce *O. sinensis*.

Some studies demonstrate that other microbial species could colonize inside sclerotia except the caterpillar fungus *O. sinensis*. *Cordyceps* related fungal species, namely, *P. hepiali*, *T. sinensis*, *P. sinensis*, *Synnematium sinense* and *Cephalosporium dongchongxiacae*, etc., most of which belong to entomopathogenic fungi, were isolated from fruiting body or sclerotia, which resulting in the debate of unique anamorph of *O. sinensis* lasted for decades. Here, aiming to explain this fact, based on our data and previous studies, we hypothesized that the larvae of *Thitarodes* sp., were infected by *O. sinensis* accompanied with degradation of insect cuticle and tissue, which drive the soil microhabitat around *O. sinensis* highly suitable for entomopathogenic fungi, improve the abundance of various types of entomopathogenic fungi and parasitize inside the sclerotia. Yet, there are significant variations of entomopathogenic fungi species in microbial community of *O. sinensis* derived from different geographical region. The present study, taking internal tissue from sterilized fruiting body and sclerotia as material, only the fungus *O. sinensis* was isolated using traditional cultivated approach. However, 5 fungal species were isolated from the sterilized sclerotia surface tissue. This result is consistent with some previous finding that total 2 unique OTUs were isolated from fruiting body, 4 OTUs from sclerotia, and 115 OTUs from mycelial cortices [9]. However, some previous data revealed that many microbial species identified from fruiting body and sclerotia, presumably, due to the fact that the soil attached to sample were not removed. Our research aimed to reveal the fungal diversity in microecosystem of *O. sinensis*, and to elucidate the role of fungal community composition in the occurrence of *O. sinensis*. Therefore, we selected the external mycelial cortices and soil microhabitat for study using coordination of culture-dependent and independent approaches.

The soil microhabitat and *O. sinensis* form a complex microecosystem, which harbour huge number of fungi, bacteria and actinomycetes. The interactions among soil microbial community might play a significant role in the infection and occurrence of *O. sinensis*. Bacterial diversity of natural *O. sinensis* was also investigated by high-throughput sequencing in our group. In external mycelial cortices, 1667 bacterial OTUs, belonging to 17

genera were identified, the predominant genera including others (48.92%), norank *Acidobacteria* (5.39%), RB41 (4.16%), *Flavobacterium* (3.15%), norank *Nitrosomonadaceae* (2.81%), *Bradyrhizobium* (2.66%), *Nitrospira* (2.42%) and norank *Anaerolineaceae* (2.01%), etc.. In soil microhabitat, 1676 bacterial OTUs, belonging to 18 genera also were identified, and 1623 bacterial OTUs were shared (unpublished data). The average relative abundance of several bacterial genera, i.e., *Flavobacterium*, *Ferruginibacter* and *Pseudomonas* were higher in external mycelial cortices, indicated that these bacterial species might enhance fungal mycelial growth and promoting the occurrence of *O. sinensis*. Recent evidence revealed that *Pseudomonas* sp. P7014 can enhance mycelial growth and reduce harvesting time of *Pleurotus eryngii* [36]. However, no studies have yet reported the best growth promoting microbes for *O. sinensis*, and it would be a hot topics.

O. sinensis and its soil microhabitat represent the potential source to explore microbial biosynthetic diversity and evolutionarily ancient examples of symbiosis, for some of *O. sinensis* associated fungi produce similar bioactive metabolites [6, 37, 38]. In microecosystem, polyketide synthase and nonribosomal peptide synthetase, the large multidomain and multifunctional megaenzymes involved in biosynthesis of secondary metabolites, evolve rapidly through horizontal transfer from bacteria to fungi, particularly, between fungi, which contribute to produce vast numbers of novel metabolites [39]. Presumably, horizontal gene transfer frequently occur in the microbiota of natural *O. sinensis* to improve the genomic flexibility and produce structurally similar metabolites during long-term symbiosis and evolution.

Previous study confirmed that the host insects of *O. sinensis* from different geographic origin are complex, mostly in the genus *Hepialus* and to a lesser extent in the genera *Hepialiscus*, *Forkalus* and *Bipectilus* [40]. Furthermore, the fungus *O. sinensis* and its hosts have co-evolved. To better clarify the structure of microbial community of *O. sinensis*, extensively collecting sampling across the geographical distribution of *O. sinensis* are necessary. However, sampling collection was affected by traffic, sample storage and shorter period of emergence of *O. sinensis*. Here, we aim to unravel fungal communities of natural *O. sinensis* using combination of high-throughput sequencing and culture-dependent approach. Therefore, *O. sinensis* samples were collected at five sites from Golog Tibetan Autonomous Prefecture of Qinghai Province, which is a suitable geographical distribution of *O. sinensis* with high quality and yield. Although the limited sampling sites covered by this study possibly result in decreasing of credibility of the present results, considerable previous studies support our data and hypothesis [19, 41].

As well know, *O. sinensis* usually occur in the humus-rich horizon of soils. Unfortunately, in present study, we did not determine the characteristics of the soil samples. Other study reveal that the pH values of habitat soils of natural *O. sinensis* range from 5.01 to 6.00, and no significant difference among different habitats. The soil microhabitat of *O. sinensis* contain a large amount of organic matters and nitrogen, which control the whole microbial community composition and affect the occurrence of *O. sinensis*. Further studies are needed to confirm the relationship between soil properties and microbial community composition and the occurrence of *O. sinensis*. In present study, we only divided the sample into external mycelial cortices and soil microhabitat. The dynamics of the hyphal bodies and its density in different distance from *O. sinensis* larvae in soil microhabitat are worthing further study, which would providing novel insight to occurrence mechanism of *O. sinensis* and be benefit to overcome the obstacle in artificial culture of *O. sinensis*.

Conclusion

This study revealed that each approach tend to capture different microbial community fractions, the significantly differences and little overlap in fungal community of natural *O. sinensis* between two approaches highlight that the combination of high-throughput sequencing and culture-dependent approaches would generate more information. A comprehensive investigation of the fungal community structure in natural *O. sinensis* performed by two approaches indicated that microbial species, namely *Trichoderma* sp., *Archaeorhizomyces*, *Sebacina*, entomogenous fungi and some bacterial species, etc., play an important role in the occurrence and maturation of *O. sinensis*. In a word, our result provide novel insights into the fungal community structure of natural *O. sinensis*, reveal the occurrence mechanism of *O. sinensis*, and would be beneficial to overcome the obstacle in artificial culture of *O. sinensis*.

Methods

Site description, sampling collection and processing

The size and shape of *O. sinensis* vary in different areas owing to the variety of infected *Thitarodes* insects, environmental factors, including plant species, soil characteristic and soil microbial community, etc.. Therefore, these *O. sinensis* samples were collected at five sites from shrubland and alpine meadow with altitude of 4000–5200 m, which distributes in the territory of Maqen County, Darlag County and Gade County, Golog Tibetan Autonomous Prefecture of Qinghai Province (97°54'–101°50' longitude, 32°31'–35°40' latitude) during May 10–20, 2015. These regions are representative geographical distribution of the *O. sinensis* with high quality

and density. Five repeats were performed by the five-point method at each site. During sampling, the naturally growing *O. sinensis* was taken as the center point, soil block with 15 cm diameter and depth of 20 cm were collected. The samples were transported to the laboratory within 24 h under controlled temperature (4 °C). Processed samples were stored at 4 °C for fungal isolation and at -80 °C for DNA extraction, respectively.

Firstly, plant residues and stones in samples were removed with a sieve. The samples derived from same site were divided into three subsamples. (i) External mycelial cortices including the mycelial cortices covering *O. sinensis* larvae and soil particles naturally attached to the surface of larvae. The names of the three repeat samples from different sites were designated as “JM-1, JM-2, JM-3”. (ii) Soil microhabitat, represent a specific areas of soil surrounding natural *O. sinensis*, in which *O. sinensis* interact with soil microbial community. The names of the three repeat samples from different sites were abbreviated as “TY-2, TY-3, TY-4”. (iii) Fruiting body of *O. sinensis* represent the part that infected fungus growing on the head of caterpillar-shaped sclerotium. Samples from external mycelial cortices and soil microhabitat were investigated using high-throughput sequencing and culture-dependent approaches, yet, fruiting body was investigated by culture-dependent approach because of little microbial species (Fig. 7).

Culture media used for fungal isolation

For best efforts to isolate fungal species from external mycelial cortices, soil microhabitat and fruiting body of natural *O. sinensis*, seven types of media were used, namely, potato dextrose agar (PDA) medium (extract from 200 g boiled potatoes, 20 g glucose, 20 g agar, 800 mL distilled water, natural pH), 1/4 PDA medium (extract from 50 g boiled potatoes, 5 g glucose, 2.5 g peptone, 15 g agar, 1000 mL distilled water, natural pH), modified PDA (I) (PDA medium+ 1% peptone+ 1% yeast extract), modified PDA (II) [PDA medium+ 1 g KH₂PO₄, 1.5 g MgSO₄·7H₂O, 0.2 g MgCl₂, 0.2 g (NH₄)₃PO₄], nutrient rich medium (10 g glucose, 10 g peptone, 10 g silkworm pupal powder, 1 g KH₂PO₄, 0.5 g MgSO₄·7H₂O, 20 g agar, 1000 mL of distilled water, pH 6.8), G medium (extract from 200 g boiled potatoes, 10 g peptone, 20 g silkworm pupae powder, vitamin B₁, 15 agar, 1000 mL distilled water, PPDA medium (PDA medium+ 1% peptone).

DNA extraction, high-throughput sequencing

For fungal community description, total genomic DNA was extracted from each subsamples, i.e., external mycelial cortices and soil microhabitat using two approaches, respectively. To improve the efficiency of the microbial DNA extraction, the samples were crushed after freezing

with liquid nitrogen in precooled mortar. The total genomic DNA extracted by two approaches were pooled for further step.

First approach. Total genomic DNA extraction from external mycelial cortices and soil microhabitat were performed using the MoBio PowerSoil DNA Isolation Kit (MoBio Laboratories, Carlsbad, CA, USA) according to manufacturer's instructions, respectively. The integrity of genomic DNA was checked by 1.0% agarose gel electrophoresis (1% w/v).

Secondary approach. Before DNA extraction, the samples were treated using TENP buffer (50 mM Tris, 20 mM EDTA, 100 mM NaCl, 0.01 g/ml Polyvinylpyrrolidone, pH 10) and PBS buffer (137 mmol/L NaCl, 2.7 mmol/L KCl, 10 mmol/L Na₂HPO₄, 2 mmol/L KH₂PO₄, pH 7.4) to remove humus. Then, the genomic DNA was extracted using the traditional method with minor modification. Briefly, For each 2 g samples, add 3 mL DNA extraction buffer, 20 μL proteinase K, 30 μL lysozyme and 20 μL lytic enzyme, mix by vortexing 30 min, add 0.5 mL 20% SDS, subsequently incubated for 2 h at 65 °C. Solution was centrifuged at room temperature 9000 r/min for 15 min, the supernatant was transferred to a new centrifuge tube. Equal volume of saturated phenol: chloroform: isoamyl alcohol (25,24,1) were used to remove protein contamination, and isopropanol was used to precipitate DNA for 30 min, followed by centrifugation at 6000×g for 30 min. Supernatant was discarded, pellet was washed with 70% ethanol, centrifuged again. Subsequently, the supernatant was removed, air dried and finally resuspended in an appropriate amount of Tris-EDTA buffer (10 mM Tris, 1 mM EDTA, pH 8.0).

The concentration and purification of mixed genomic DNA extracted using the above two approaches were determined by NanoDrop 2000 UV-vis spectrophotometer (Thermo Scientific, Wilmington, USA), the fungal rDNA ITS1 regions were amplified from the mixed total genomic DNA with primers ITSIF (5'-CTTGTCATT TAGAGGAAGTAA-3') and ITS2R (5'-GCTGCGTTCT TCATCGATGC-3') by the ABI GeneAmp® 9700 PCR System (Applied Biosystems, Waltham, MA, USA) [42]. The PCR reaction mixture (20 μL) contained 4 μL of 5× FastPfu Buffer, 2 μL of dNTPs (2.5 mM), 0.8 μL of each primer, 0.4 μL of FastPfu Polymerase, 10 ng of template DNA. The PCR procedures were 95 °C for 3 min initial denaturation, 27 cycles of 30 s at 95 °C, 30 s for annealing at 55 °C, 45 s for elongation at 72 °C, and a final extension at 72 °C for 10 min. Triplicate PCR reactions were carried out for each sample, the products were mixed, and evaluated by 2% agarose gel electrophoresis. The mixed products were purified using the AxyPrep DNA Gel Extraction Kit (Axygen Biosciences, Union City, CA, USA) and quantified using QuantiFluor™-ST (Promega, USA). Purified amplicons were pooled in equimolar and

Fig. 7 Natural habitat and collection of *O. sinensis* samples. **a** Natural habitat for collecting *O. sinensis* samples; **b** Growing *O. sinensis*; **c** Soil microhabitat surrounding natural *O. sinensis*; **d** External mycelial cortices including the mycelial cortices covering *O. sinensis* larvae and soil particles naturally attached to the surface of larvae

paired-end sequenced (2×300) on an Illumina MiSeq platform (Illumina, San Diego, USA) according to the standard protocols by Majorbio Bio-Pharm Technology Co. Ltd. (Shanghai, China). Raw sequencing data obtained from this study were deposited at DDBJ/ENA/GenBank under the accession numbers: PRJNA609607.

Processing of sequencing data

Raw FASTQ files were demultiplexed, quality-filtered by Trimmomatic, and merged by the following criteria: (i) The reads were truncated at any site receiving an average quality score < 20 over a 50 bp sliding window. (ii) Primers were exactly matched allowing 2 nucleotide mismatching, and reads containing ambiguous bases were removed. (iii) Sequences whose overlap longer than 10 bp were merged according to their overlap sequence. After quality control, the reads were clustered into OTUs according to the pipeline of QIIME commands based on 97% sequence similarity. Representative sequences of each OTU were blasted against the UNITE database to obtain taxonomy with a threshold value of 0.8. The α -diversity indices, including ACE index, Chao1 index, Shannon index, Simpson index, and Coverage were calculated using Mothur 1.30.1. Euclidean-based Weighted UniFrac distances were employed to determine the distance (β -diversity) between fungal communities in any pair of samples. Venn diagrams were generated to illustrate the proportion of shared and unique taxa between different samples. The hierarchical clustering graph was generated using the MeV software, version 4.9.0 and the hierarchical clustering method.

Principal coordinates analysis (PCoA) is a visualization method for studying variation in data, based on UniFrac metrics, and is useful for describing the species composition similarity between samples. In present study, PCoA was performed using the vegan package 2.0–10. All software used was in Mothur package.

Isolation and identification of culturable fungi

The culturable fungi were isolated from the external mycelial cortices and soil microhabitat, which were pooled from all samples derived from different sites by the dilution-plate approach. A total of 10 g samples were added to a triangular flask containing 90 mL of sterile water and glass beads, shaking at 180 r/min for 1 h at 16 °C, to prepare a suspension with a concentration of 10^{-1} , then serially diluted with sterile water to a concentration of 10^{-2} – 10^{-6} . A total of 200 μ L of each dilution were plated with triplicates in seven types of media. All of which contain 100 μ g/mL streptomycin, 100 μ g/mL penicillin and 10 mg/L rose bengal. The Petri dishes were incubated at 16 °C in dark, and the characteristic of each emerging fungal colony was observed daily, then transferred onto a new PDA plate, until axenic cultures were obtained.

Fruiting body and sclerotia of *O. sinensis* were rinsed with sterile water, surface-sterilized using 75% ethanol for 3 min, followed by 2.5% sodium hypochlorite (NaClO) for 25 min, rinsed twice in sterile distilled water, dried on sterile filter paper. Subsequently, the internal tissue blocks obtained from the fruiting body and sclerotia of sterilized *O. sinensis*, were cut into 1–2 mm slice, then placed on different media described above. The Petri dishes were

incubated at 16 °C in dark. While hyphae germinate and grow from the tissue slice, the tip of hyphae were picked to purify culturable fungal species.

Effectiveness of surface sterilization: the surface-sterilized samples were washed in sterile distilled water three times, soaked in 1.5 mL sterile water, and stirred for 1 min. A total of 100 µL suspension were inoculated onto modified PDA (I) medium plates at 16 °C in dark. If no microbial growth occurred on the medium, the sterilization was considered complete.

Identification of culturable fungal isolates

The purified fungal isolates were categorized preliminarily based on colony characteristics, including colony morphology, texture, aerial hyphae, substrate hyphae, spore mass color, sporophore and spore chain morphology, distinctive reverse colony color and diffusible pigment, etc.. The representative fungal isolates with distinct morphology were identified using a combination of morphology characteristics and the ITS sequence. The extraction of genomic DNA were performed using CTAB methods as previously described [43].

The nearly full-length ITS region of the rDNA gene was amplified by the primers ITS1 (5'-TCCGTAGGTG AACCTGCGG-3') and ITS4 (5'-TCCTCCGCTTATTG ATATGC-3') [44]. The amplicons were purified using the ExoSAP-IT reagent (USB Corporation, Cleveland, OH) following manufacturer's instructions, ligated into pMD18-T (TaKaRa, Japan) and transformed into competent *E.coli* DH5a following the manufacturer's protocol. The positive transformants were sent to Shanghai Invitrogen Biotechnology Co. Ltd., for sequencing. The sequences of fungal rDNA ITS region were compared with that of the most closely-related fungal species (higher than 97% similarity) in the NCBI database using the BLAST program. The ITS sequence data were submitted and deposited in GenBank under accession numbers MT133906-MT134006.

Authors' contributions

CBZ designed and organized this study, wrote and revised the manuscript. CHR performed most of the experiments. YLW collected samples and analyzed the sequence data. QQW and YSW analyzed and submitted sequence data to Gene Bank. QBW gave advice for revision of this manuscript. All authors read and approved the final manuscript.

Funding

This work was supported by the National Natural Science Foundation of China (No. 81460585, 81760688). The funds are mainly used for fungal community of

O. sinensis, biosynthesis and biotransformation. This work was jointly supported by scientific and technological research for social development of Guizhou Province, China [No. (2013)3154] and Provincial Program on Platform of Guizhou China (Grant No:[2019]5617).

Availability of data and materials

The datasets used and analysed during the current study are available from the corresponding author on reasonable request. The raw reads of MiSeq data were also deposited into the NCBI Sequence Read Archive database under accession numbers: PRJNA609607. All the ITS sequence data of 77 culturable fungal isolates have been upload to NCBI database under accession numbers: MT133906-MT134006.

Publisher's Note

Springer Nature remains neutral with regard to jurisdictional claims in published maps and institutional affiliations.

Ready to submit your research? Choose BMC and benefit from:

- fast, convenient online submission
- thorough peer review by experienced researchers in your field
- rapid publication on acceptance
- support for research data, including large and complex data types
- gold Open Access which fosters wider collaboration and increased citations
- maximum visibility for your research: over 100M website views per year

At BMC, research is always in progress.
