Abstract:

Objective Sodium-glucose co-transporter 2 (SGLT2) inhibitors reduce cardiovascular events and decrease the body fat mass in patients with type 2 diabetes mellitus (T2DM). We examined whether or not the SGLT2-inhibitor dapagliflozin can improve the endothelial function associated with a reduction in abdominal fat mass.

Methods We prospectively recruited patients with uncontrolled [hemoglobin A1c (HbA1c) >7.0%] T2DM who were not being treated by SGLT2 inhibitors. Patients were treated with add-on dapagliflozin (5 mg/day) or non-SGLT2 inhibitor medicines for 6 months to improve their HbA1c. We measured the peripheral microvascular endothelial function as assessed by reactive hyperemia peripheral arterial tonometry (RH-PAT) and calculated the natural logarithmic transformed value of the RH-PAT index (LnRHI). We then investigated changes in the LnRHI and abdominal fat area using computed tomography (CT).

Results The subjects were 54 patients with uncontrolled T2DM (72.2% men) with a mean HbA1c of 8.1%. The HbA1c was significantly decreased in both groups, with no significant difference between the groups. Dapagliflozin treatment, but not non-SGLT2 inhibitor treatment, significantly increased the LnRHI. The changes in the LnRHI were significantly greater in the dapagliflozin group than in the non-SGLT2 inhibitor group. Dapagliflozin treatment, but not non-SGLT2 inhibitor treatment, significantly decreased the abdominal visceral fat area, subcutaneous fat area (SFA), and total fat area (TFA) as assessed by CT and significantly increased the plasma adiponectin levels. The percentage changes in the LnRHI were significantly correlated with changes in the SFA, TFA, systolic blood pressure, and adiponectin.

Conclusion Add-on treatment with dapagliflozin significantly improves the glycemic control and endothelial function associated with a reduction in the abdominal fat mass in patients with uncontrolled T2DM.

Key words: sodium-glucose co-transporter 2 inhibitor, endothelial function, fat mass, type 2 diabetes

(DOI: 10.2169/internalmedicine.0701-17)

Introduction

Sodium-glucose co-transporter 2 (SGLT2) inhibitors exert their glucose-lowering effects via the inhibition of SGLT2 protein in the kidney proximal tubule. This results in the im-

provement of the glycemic control in patients with type 2 diabetes mellitus (T2DM) by an insulin-independent glucose-lowering action accompanied by body weight loss, mainly with a reduction in the fat mass (1-3). Obesity and fat accumulation are major fundamental pathogenic conditions in patients with T2DM (4). In patients with uncon-

trolled T2DM under treatment with pre-existing anti-diabetic medications, physicians clinically expect greater improvement of the glycemic control through the novel glucose-lowering benefits of add-on SGLT2 inhibitors (5, 6).

In cardiovascular safety studies of add-on treatment of SGLT2 inhibitors, the EMPA-REG OUTCOME[®] trial of empagliflozin and cardiovascular assessment study (CANVAS) of canagliflozin showed not only its cardiovascular safety but also its superiority with regard to reducing major adverse cardiovascular events in high-risk T2DM (7, 8). At present, the potential mechanisms of SGLT2 inhibitors for preventing cardiovascular event have not been fully determined (9). Recent clinical studies have shown that SGLT2 inhibitors have beneficial effects on the vascular function in patients with DM (10-12). However, the practical effects of add-on treatment of dapagliflozin on improving the glycemic control and microvascular endothelial dysfunction have not been investigated in patients with uncontrolled T2DM.

T2DM is considered a strong, major clinical risk factor for developing atherosclerosis and cardiovascular diseases (13). Vascular endothelial dysfunction is a significant and independent predictor of future cardiovascular events (14, 15). The presence of T2DM has been recognized as a crucial pathological condition leading to endothelial dysfunction in clinical practice (16). Increased attention has been focused on investigating and developing practical strategies for improving the vascular endothelial function clinically (17). Glucose-lowering therapies that may show favorable effects on the endothelial function are thought to have additionally clinical value for managing DM (18). SGLT2 inhibitors have been reported to improve glycemic control by reducing body fat mass (2, 3, 19). Therefore, SGLT2 inhibitors could provide clinical and cardiovascular benefits by improving the endothelial function and decreasing the body fat mass.

In the present study, we hypothesized that add-on dapagliflozin treatment would improve the glycemic control and endothelial function by reducing the abdominal fat mass. Therefore, we investigated the effects of add-on dapagliflozin therapy on the peripheral microvascular endothelial function in patients with uncontrolled T2DM [hemoglobin A1c (HbA1c) >7.0%]. The peripheral microvascular endothelial function was assessed by a reactive hyperemia-peripheral arterial tonometry (RH-PAT) examination and abdominal fat area was measured by computed tomography (CT).

Materials and Methods

Study population and study protocol

We prospectively recruited Japanese patients with stable but uncontrolled (HbA1c >7.0%) T2DM without severe obesity [body mass index (BMI) <35 kg/m²] who had not taken SGLT2 inhibitors before from the Diabetes Care Center in Jinnouchi Hospital between 2014 and 2017. The exclusion

criteria were as follows: type 1 DM, insulin-dependent condition [fasting C-peptide immunoreactivity (CPR) <0.6 ng/mL], a history of ketoacidosis, age >80 years, unstable cardiovascular disease, active inflammation, severe liver disease, dementia, chronic kidney disease (estimated glomerular filtration rate <30 mL/min/1.73 m²), urinary tract infection, cancer, and those who could not remain standing to have a body composition examination. Patients with newly diagnosed DM without any treatments were also excluded. We performed an RH-PAT examination in the morning, and patients with good endothelial function [reactive hyperemia index (RHI) >2.10] were also excluded.

The attending physicians at Jinnouchi Hospital non-randomly separated the enrolled patients into two groups: the dapagliflozin group and the non-SGLT2 inhibitor group. Inclusion in the treatment arm was left to the physicians' discretion. Patients in the dapagliflozin group received their ongoing treatments and additional dapagliflozin (5 mg/day) for 6 months. Patients in the non-SGLT2 inhibitor group received their ongoing treatments along with intensification of glucose-lowering medications (increased doses and addition of other types of medications) without SGLT2 inhibitors to achieve an HbA1c level <7.0% by the end of the study period.

Before starting treatment, a fasting blood sample was collected from the antecubital vein in the morning. The body composition was measured by a bioelectrical impedance analysis using the InBody770[®] (Biospace, Seoul, Korea) and plain abdominal CT (Aquilion CXL[®]; Toshiba, Tokyo, Japan). After 6 months of treatment, another fasting blood sample was collected, and a second body composition analysis using the InBody770[®], plain abdominal CT, and an RH-PAT examination was performed.

The primary outcome was the dapagliflozin-induced changes in the endothelial function as assessed by an RH-PAT examination as a prospective, parallel-arm, open-label study. This study was conducted in accordance with the Declaration of Helsinki. The study protocol was approved by the Human Ethics Review Committee of Jinnouchi Hospital (2014-5-4), and a signed consent form was obtained from each patient. This study was registered under the UMIN protocol registration system (ID UMIN0000333354).

Measurement of the peripheral microvascular endothelial function by an RH-PAT examination

The principles and details of the RH-PAT examination have been described previously (20, 21). In brief, we volumetrically evaluated the peripheral microvascular endothelial function in the fingertip by RH-PAT using an Endo-PAT 2000[®] device (Itamar Medical, Caesarea, Israel). Measurements were taken when patients were in a stable condition and in the fasting state in the early morning before taking their medications. Patients were examined on a bed in the supine position after at least 10 minutes of rest in a temperature- and light-controlled environment. A blood pressure cuff was placed on the upper arm to be studied, while

the contra-lateral arm served as a control. PAT probes were placed on one finger of each hand. After an equilibration period, the baseline pulse volume amplitude was measured for each fingertip for 5 minutes. The cuff was inflated to 60 mmHg above systolic pressure or 200 mmHg for 5 minutes before being deflated to induce reactive hyperemia. After cuff deflation, PAT recordings were performed for 10 minutes, and RH-PAT data were automatically analyzed in real time using a software program (Endo-PAT2000[®] software, version 3.5.4; Itamar Medical). The RHI reflects the extent of reactive hyperemia and was calculated as the ratio of the average amplitude of the PAT signal over 1.0 minutes starting 1.5 minutes after deflation of the cuff (control arm, A; occluded arm, C) divided by the average amplitude of the PAT signal at 2.5 minutes before inflation of the cuff (baseline: control arm, B; occluded arm, D) according to the following equation:

$$(C/D) / (A/B); (20)$$

We calculated the natural logarithmic transformation (Ln) of the RHI (LnRHI) (14).

Measurement of the body composition using a bioelectrical impedance analyzer (InBody770[®])

Anthropometric measurements were obtained in the standing position. Elementary body composition, including total fat mass and body fat percentage, was measured using a direct segmental multi-frequency bioelectrical impedance analyzer (InBody770[®]) (22). This analyzer processes 30 impedance measurements using 6 different frequencies (1, 5, 50, 250, 500, and 1,000 kHz) at each of 5 segments of the body (right arm, left arm, trunk, right leg, and left leg). In addition, measurements are processed by 15 reactance measurements using tetrapolar 8-point tactile electrodes at 3 different frequencies (5, 50, and 250 kHz) at each of 5 segments of the body (right arm, left arm, trunk, right leg, and left leg) (23).

Measurement of the visceral fat area and subcutaneous fat area using abdominal CT

On CT slices that were obtained at the umbilical level, the adipose tissue area located in the peritoneal cavity was defined as the visceral fat area (VFA: cm²), and the adipose tissue area underlying the skin layer was defined as the subcutaneous fat area (SFA: cm²). The VFA and SFA were measured on CT cross-sectional scans obtained at the umbilical level in the supine position (24) using a commercial software program based on the Japanese guidelines of obesity treatment (Japan Society for the Study of Obesity, in Japanese). The total fat area (TFA: cm²) was the sum of the SFA and VFA.

Blood sampling and the measurement of clinical parameters

Fasting blood samples were collected from the antecubital vein in the morning. Blood analyses were conducted in the hospital laboratory to measure the levels of hemoglobin, he-

matocrit, blood glucose, HbA1c, cholesterol, triglycerides, CPR, creatinine, and B-type natriuretic peptide (BNP). The levels of adiponectin, non-esterified fatty acid (NEFA), glucagon, and total ketone bodies were measured by SRL (Tokyo, Japan).

Outcomes

The primary endpoint was the treatment-induced changes in the endothelial function as assessed by an RH-PAT examination using an Endo-PAT2000[®]. We tested the superiority of the dapagliflozin-induced changes in the LnRHI compared with non-SGLT2 inhibitor therapy following a six-month course of treatment. The secondary outcome was the relationship between the percentage changes in the LnRHI and changes in fat mass and other clinical parameters.

Statistical analyses

Based on our preliminary examination at our hospital, a power analysis indicated that an enrollment of more than 48 patients was required to detect a mean difference in the change in the LnRHI of 0.15 in the dapagliflozin group and 0.05 in the non-SGLT2 inhibitor group, with a standard deviation of 0.15, a power of 90%, and a 2-sided alpha of 0.05. The results of normally distributed continuous variables (determined by the Shapiro-Wilk test) were expressed as the mean [standard deviation (SD)], while those of continuous variables with a skewed distribution were expressed as median values (interquartile range). Differences in the baseline characteristics of the two groups were analyzed by Student's *t*-test, the Mann-Whitney U test, or Fisher's exact test for categorical data, as appropriate. Either a paired Student's *t*-test or Wilcoxon's test was used to analyze the effect of each treatment. The difference between treatment groups in changes in the LnRHI from baseline to six months was also assessed using an analysis of covariance (ANCOVA) with adjustment for baseline measures as covariates (pre-LnRHI, age, duration of DM, pre-HbA1c, body weight, and systolic blood pressure).

To determine the relationships between changes in various clinical parameters and percentage changes in the LnRHI, correlations between variables of interest were analyzed using Pearson's correlation coefficient. Patients with an increase in the LnRHI >15.0% were defined as having an improved endothelial function in the present study (25). A logistic regression analysis was used to evaluate the association between improvement in the endothelial function and baseline clinical variables, including the age, sex, BMI, HbA1c, fasting plasma glucose (FPG), lipid parameters, medications, and therapy allocation (dapagliflozin or non-SGLT2 inhibitor therapy). Associations between groups and all other parameters were analyzed first by a univariate logistic regression analysis. This was followed by a multivariate logistic regression analysis using the forced inclusion model, and the Hosmer-Lemeshow goodness-of-fit statistic was calculated. A *p* value <0.05 was considered statistically significant. Statistical analyses were performed using the

Results

Baseline clinical characteristics of the study subjects

A total of 54 Japanese patients with uncontrolled T2DM were enrolled and non-randomly assigned to the 2 groups. All of the patients completed the study protocol. The clinical baseline characteristics of the total patients and those of each group are shown in Table 1. The mean age was 56.1 years, 72.2% were men, the mean BMI was 27.1 kg/m², the mean HbA1c was 8.1%, and the mean FPG level was 143.2 mg/dL. At enrollment, 44.4% of patients were treated with insulin, and the frequency of the baseline anti-diabetic medications was not significantly different between the groups. The baseline characteristics of patients in the dapagliflozin group were similar to those of the non-SGLT2 inhibitor group. The BMI, HbA1c levels, FPG levels, and duration of DM were not significantly different between the groups.

Changes in the HbA1c, FPG, glucagon, and CPR

At the end of the study period, 5 mg/day of dapagliflozin was used for the dapagliflozin group. In the non-SGLT2 inhibitor group, the doses of previously prescribed medications were increased in 82.6% of the patients, and new medications were administered to 33.3% of the patients. The total patients in both treatment groups showed a significant improvement in HbA1c [median (interquartile range): pre-treatment to post-treatment, 7.9% (7.3-8.7%) to 6.9% (6.5-7.5%), $p<0.01$] and FPG levels (mean±SD: 143.2±38.7 to

125.1±27.2 mg/dL, $p<0.01$) at 6 months. As shown in Table 2, the HbA1c levels were significantly decreased in both groups, while the absolute changes in the HbA1c and FPG levels were not significantly different between the dapagliflozin and non-SGLT2 inhibitor groups. We did not find any marked changes in the fasting plasma glucagon levels in either group. Dapagliflozin treatment significantly decreased the fasting blood CPR levels.

Changes in the body weight, total body fat mass, and abdominal fat area as assessed by CT

Dapagliflozin treatment, but not non-SGLT2 inhibitor treatment, for 6 months significantly decreased the body weight (mean±SD; -4.4±3.2%, $p<0.01$) and total fat mass (mean±SD; -12.1±11.3%, $p<0.01$) compared with the baseline (Table 2). Dapagliflozin treatment, but not non-SGLT2 inhibitor treatment, also significantly decreased the waist circumference (mean±SD; -3.2±5.4%, $p<0.01$), abdominal VFA (mean±SD; -21.2±15.2%, $p<0.01$), SFA (mean±SD; -12.4±15.1%, $p<0.01$), and TFA (mean±SD; -14.9±13.3%, $p<0.01$) compared with the baseline.

Changes in the blood pressure, heart rate, and other metabolic parameters

As shown in Table 3, dapagliflozin treatment, but not non-SGLT2 inhibitor treatment, significantly decreased the blood pressure at six months compared with the baseline, as reported previously (26). Furthermore, the heart rate in the dapagliflozin treatment group was also significantly decreased at six months compared with the baseline. The hematocrit and hemoglobin levels were significantly increased in the dapagliflozin treatment group at six months compared with the baseline, with no marked changes in the non-

SGLT2 inhibitor group. The BNP levels appeared to be decreased at six months compared with the baseline in the dapagliflozin treatment group, but this was not significant. The absolute changes in the BNP levels were not significantly different between the two groups. The total cholesterol levels, low-density lipoprotein cholesterol levels, NEFA levels, and estimated glomerular filtration rate did not show significant changes in either group. The plasma total ketone body levels were significantly increased in the dapagliflozin group at six months compared with the baseline, but there were no marked changes in the non-SGLT2 inhibitor group (Table 3). The triglyceride levels were significantly decreased in the dapagliflozin group at six months compared with the baseline, but the absolute changes in triglyceride levels were not significantly different between the two groups. Dapagliflozin treatment, but not non-SGLT2 inhibitor treatment, significantly increased the plasma adiponectin levels at six months compared with the baseline. The absolute changes in adiponectin levels were significantly greater in the dapagliflozin group than in the non-SGLT2 inhibitor group.

Changes in the endothelial function as assessed by an RH-PAT examination

During 6 months of treatment, the peripheral microvascu-

lar endothelial function, as assessed by the LnRHI, was significantly improved after glucose-lowering therapy in the total patients (LnRHI: 0.450±0.125 to 0.592±0.228, p<0.01). Add-on dapagliflozin-therapy, but not non-SGLT2 inhibitor therapy, resulted in a significant intra-group improvement in the endothelial function (dapagliflozin group: 0.450±0.135 to 0.662±0.230, p<0.01; non-SGLT2-inhibitor group: 0.450±0.118 to 0.522±0.208, p=0.09; Table 3). With regard to inter-group comparisons, the absolute changes and percentage changes in the LnRHI were significantly greater in the dapagliflozin group than in the non-SGLT2 inhibitor group (p=0.028; Table 3 and Fig. 1). An ANCOVA with adjustment for the various baseline parameters revealed that the changes in the LnRHI were significantly greater in the dapagliflozin group than in the non-SGLT2 inhibitor group (ANCOVA, p=0.034).

A logistic regression analysis for improvements in the endothelial function

The proportion of patients with an improved endothelial function (percentage increase in LnRHI >15%) was 74.1% in the dapagliflozin group and 40.7% in the non-SGLT2 inhibitor group (Fig. 2, p=0.01). A univariate logistic regression analysis showed that dapagliflozin therapy was signifi-

†p<0.01, ‡p<0.05 Dapagliflozin versus Non-SGLT2i. SGLT2i: sodium glucose co-transporter 2 inhibitor, BP: blood pressure, BNP: B-type natriuretic peptide, eGFR: estimated glomerular filtration rate, NEFA: non-esterified fatty acid, LnRHI: natural logarithmic transformation of reactive-hyperemia index

cantly correlated with an improvement in the endothelial function (Table 4). A forced inclusion multivariate logistic regression analysis with the BMI and dapagliflozin therapy showed that only dapagliflozin therapy was significantly correlated with an improvement in the endothelial function (odds ratio: 3.931, 95% confidence interval: 1.217 to 12.695, p=0.022). The Hosmer-Lemeshow statistic was appropriate (p=0.14).

The association between changes in the clinical and metabolic parameters and changes in the LnRHI

To determine the factors associated with improvement in the endothelial function as assessed by the percentage increase in the LnRHI and the changes in various clinical and laboratory parameters during the treatment period, we investigated the correlation coefficients between the percentage increase in the LnRHI and changes in the variables. The percentage change in the LnRHI was not significantly corre-

lated with changes in the body weight, BMI, HbA1c levels, or FBG levels (Table 5). However, the percentage change in the LnRHI was significantly correlated with changes in the TFA, SFA, systolic blood pressure, and adiponectin levels. Changes in the waist circumference, as a simple anthropometric parameter of abdominal fat deposition, showed a non-significant correlation with the percentage change in the LnRHI.

Discussion

In patients with uncontrolled T2DM, add-on treatment of the SGLT2 inhibitor dapagliflozin for 6 months significantly improved the peripheral microvascular endothelial function as assessed by an RH-PAT examination. Dapagliflozin is a clinically useful and promising anti-diabetic treatment tool for improving the glycemic control and endothelial function, accompanied by a reduced blood pressure and abdominal fat

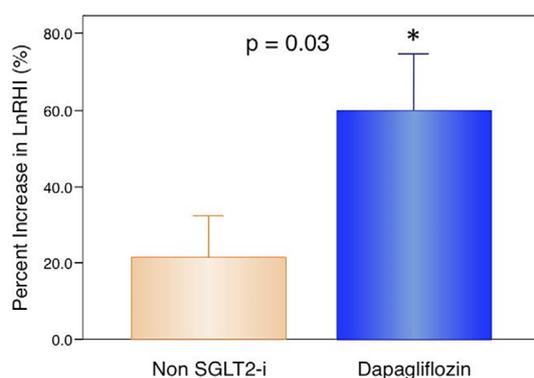

Figure 1. Percentage changes in the peripheral microvascular endothelial function as assessed by an RH-PAT examination in dapagliflozin therapy and non-SGLT2 inhibitor therapy. Bar graphs depict the changes in the natural logarithmic transformation of reactive hyperemia index (LnRHI) values (mean and standard error) in patients with dapagliflozin therapy (n=27) or non-sodium-glucose co-transporter 2 (SGLT2) inhibitor therapy (n=27). Percentage increase in LnRHI=[(LnRHI after 6 months of therapy)-(LnRHI at enrollment)] \times 100/ (LnRHI at enrollment). With regard to the inter-group comparison, the changes in the LnRHI in patients with dapagliflozin therapy were significantly greater than those in the patients with non-SGLT2 inhibitor therapy (unpaired t-test, $p=0.03$). Six months of dapagliflozin therapy significantly increased the LnRHI compared with the baseline (paired t-test, $*p<0.01$).

mass and increased plasma adiponectin levels in patients with T2DM.

DM is a major clinical risk factor for developing atherosclerosis and endothelial dysfunction, leading to an increased occurrence of cardiovascular complications (13). A meta-analysis showed that intensive glucose-lowering therapies were markedly effective at reducing the rate of myocardial infarction and coronary heart diseases (27). Therefore, effective glucose-lowering treatment strategies that have a favorable action on the endothelial function are thought to have additional clinical value in the management of DM (18). Thiazolidinediones significantly improved the endothelial function in a meta-analysis (28). In addition, Matsubara et al. showed that the DPP-4 inhibitor sitagliptin significantly improved the endothelial function in patients with T2DM and coronary artery disease (21). Torimoto et al. found that the glucagon-like peptide-1 receptor agonist exenatide improved postprandial vascular endothelial dysfunction after the meal loading test (29). In the present study, we clearly showed that add-on dapagliflozin for six months significantly improved the microvascular endothelial function in patients with uncontrolled T2DM. In cardiovascular safety studies, such as the EMPA-REG OUTCOME[®] trial and CANVAS program, add-on therapies of SGLT2 inhibitors proved effective in preventing major adverse cardiovascular events in high-risk T2DM patients (7, 8). SGLT2 inhibitors exert their novel glucose-lowering effects via insulin-

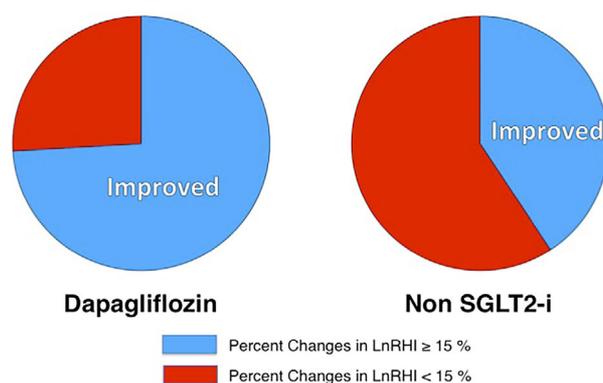

Figure 2. Pie charts of the proportion of patients with an improved endothelial function who received dapagliflozin therapy and non-SGLT2 inhibitor therapy. The proportion of patients with an improved endothelial function was 74.1% in the dapagliflozin group and 40.7% in the non-SGLT2 inhibitor group ($p=0.013$). LnRHI: natural logarithmic transformation of the reactive hyperemia index, SGLT2-I: sodium-glucose co-transporter 2 inhibitor

independent mechanisms (5). In the present study, dapagliflozin exerted a beneficial vascular action by improving the microvascular endothelial function. Therefore, dapagliflozin may be a promising medication for improving the glycemic control and resolving endothelial dysfunction in patients with uncontrolled T2DM.

The detailed mechanisms underlying the prevention of cardiovascular events by SGLT2 inhibitors have not been fully determined. However, some potential vascular benefits of reducing the blood pressure and arterial stiffness have been reported (9). Shigiyama et al. recently demonstrated that add-on dapagliflozin with low-dose metformin tended to improve the endothelial function as assessed by flow-mediated vasodilation (FMD) compared with an increasing dose of metformin in the early stage of T2DM (11). In their sub-group analysis, dapagliflozin significantly improved the endothelial function only in patients with uncontrolled T2DM. They suggested that dapagliflozin might improve the endothelial function through a reduction in the oxidative stress as evaluated by urinary levels of 8-hydroxy-2'-deoxyguanosin (11). Solini et al. recently reported that 2-day dapagliflozin treatment rapidly and significantly improved the endothelial function as assessed by FMD in patients with T2DM (12). They also proposed a potential mechanism underlying the dapagliflozin-induced improvement of the vascular function via a reduction in the oxidative stress as assessed by urinary isoprostanes.

We cannot speculate on the possible involvement of reducing oxidative stress in improving the endothelial function by dapagliflozin in our study because we did not measure any markers of oxidative stress. Dapagliflozin therapy may reduce oxidative stress through several pathways and metabolic changes, including improvement of the glycemic control, elevation of adiponectin, and a reduction in triglyceride levels, the blood pressure, the body weight, and the fat

mass.

SGLT2 inhibitors exerted blood pressure-lowering effects in a previous meta-analysis (26). We also confirmed the beneficial effects of dapagliflozin on the blood pressure in the present study. A previous study showed that 2-day dapagliflozin treatment improved the endothelial function, independent of blood pressure-lowering effects (12). However, we found a significant correlation between the degree of improvement in the endothelial function and the reduction in systolic blood pressure in our six-month study. We speculate that the endothelial function improved by dapagliflozin might subsequently induce the functional recovery of impaired microcirculation and abnormal vasomotion of arterioles with increased vascular tone, thereby leading to a reduction in the systemic blood pressure.

Obesity and fat accumulation are major fundamental pathogenic conditions in patients with T2DM (30). Glucose-lowering treatment strategies that can provide a reduction in the body weight and fat mass are thought to have additive clinical advantage in the management of DM (4). The post-hoc results of the Look AHEAD study showed the cardiovascular benefits of practically achieved weight reduction during the long-term management of T2DM (31). Matsuzawa et al. reported that the waist circumference, reflecting abdominal obesity, was strongly associated with endothelial dysfunction in patients with metabolic syndrome (32). They also found that the degree of reduction in the waist circumference by lifestyle modifications was substantially correlated with improvement in the endothelial function. The current study showed a significant correlation between the

dapagliflozin-induced improvement in the endothelial function and changes in the plasma adiponectin levels and abdominal fat mass, particularly SFA, as assessed by abdominal CT. Adiponectin has athero-protective effects and improves the endothelial function (33). Because SGLT2 inhibitors improve the glycemic control via the reduction in the body weight and fat mass (2), SGLT2 inhibitors may be able to achieve cardiovascular benefits by improving the endothelial function, accompanied by a decrease in the abdominal fat mass and an increase in the plasma adiponectin levels. Recent experimental approaches to examining the mechanism underlying the effects of SGLT2 inhibitors on the vascular function have suggested that the effects of SGLT2 inhibitors on the endothelial function may be independent of a reduction in fat (34, 35). Further studies are required to clarify the precise mechanisms underlying the effects of SGLT2 inhibitors on the endothelial function.

Adiponectin is secreted by adipocytes, and the decreased plasma levels of adiponectin play an important role in the pathogenesis of T2DM and cardiovascular diseases (33). Adiponectin levels are reported to be inversely correlated with both the total and abdominal fat mass (36). Thiazolidinediones, PPAR γ agonists, have been shown to increase the circulating levels of adiponectin in humans (37). We observed increased plasma adiponectin levels in patients receiving dapagliflozin therapy in the present study, although the detailed molecular mechanisms underlying this dapagliflozin-induced elevation remain unclear. A reduction in both the visceral and subcutaneous fat mass helps increase the adiponectin level through lifestyle intervention in patients with T2DM (38). Because adipocytes do not express SGLT2, the direct effects of dapagliflozin on adipocytes may not play a central role in the present results. We instead speculate that the effects of dapagliflozin-induced fat mass reduction via urinary calorie loss may modulate the functions and metabolism of adipocytes, leading to the elevation of plasma adiponectin.

At present, only two clinical studies with dapagliflozin have shown improving effects of SGLT2-inhibitors on the endothelial function (11, 12). In *in vivo* animal models, dapagliflozin treatment (35), empagliflozin treatment (39), and ipragliflozin treatment (34) improved the endothelial function. However, we lack sufficient clinical data at present regarding the SGLT2 inhibitor-induced improvement in the endothelial function as a drug class effect.

Our study has several limitations, including the small number of subjects, non-random allocation, open-label design, relatively short study period, and possible bias in patient selection. More detailed and longer studies are required to validate the effects of SGLT2 inhibitor treatment on improving the endothelial function as demonstrated in the present study. The beneficial effects of SGLT2 inhibitors on the endothelial function should be confirmed in larger, randomized clinical studies (40). This study included patients with uncontrolled T2DM (HbA1c >7.0%) as well as patients without severe obesity (BMI >35 kg/m²). Further studies

evaluating the effects of dapagliflozin on the endothelial function should be considered in patients with T2DM with a normal weight, severe obesity, older age, and well-controlled DM. In addition, the detailed mechanisms underlying the dapagliflozin-induced improvement in the endothelial function could not be determined in the present clinical study. We were also unable to measure markers of inflammation and oxidative stress. Prospective studies including these biomarkers may help determine the underlying mechanisms of action of SGLT2 inhibitors.

Conclusion

Add-on treatment with dapagliflozin significantly improves the glycemic control and endothelial function associated with a reduction in the abdominal fat mass in patients with uncontrolled T2DM.
