Several studies have reported common presentations accompanying immunoglobulin G (IgG) antibodies targeting the neuronal cell adhesion protein IgLON5.^{1–3} Complex sleep and movement disorders, gait imbalance, and bulbar symptoms are prominent features. Here, we report an unusual manifestation of subacute onset encephalitis with spontaneous recovery accompanying IgLON5 autoimmunity.

Case description

A 73-year-old man with a remote renal oncocytoma history, and 2 years of difficulty with sleep initiation and maintenance, had 3 weeks of progressive gait imbalance, constipation, worsened insomnia, and confusion, followed by 5 days of headache, subjective chills, and fever. Initial testing revealed an elevated CSF protein level alone (103 mg/dL). Over 2 days, the patient continued to deteriorate, eventually requiring intubation for airway protection. On transfer to Mayo Clinic, empiric antimicrobials, antiepileptics, and dexamethasone initiated at the outside hospital were not continued. Repeat CSF studies demonstrated an elevated protein level (194 mg/dL) and 50 nucleated white blood cells/ μ L (normal $\leq 5/\mu$ L; monocyte predominant). Brain MRI revealed subtle T2 hyperintensities in the hypothalamus (figure, A and B). His neurologic status improved briskly over days with supportive care alone. He was discharged to an acute rehabilitation unit within 1 week and returned home thereafter. His serum and CSF from that hospitalization both harbored IgLON5-IgG antibodies, detected by tissue-based indirect immunofluorescence assay and confirmed by IgLON5-transfected cell-based assay.³

At 6-month follow-up, the patient reported mild residual symptoms (fatigue and insomnia without excessive daytime sleepiness, gait imbalance, and memory and word-finding difficulties). He also described occasional dysphagia, hoarseness, sialorrhea, and emotional lability, which were absent before his hospitalization. Urinary retention present during his hospitalization had resolved within weeks of onset. There were no reports of complex sleep behaviors or sleep breathing difficulties. His neurologic examination was normal. Repeat brain MRI showed residual T2 hyperintensities in the hypothalamus (figure, C). His symptoms remained stable at 1 year. Polysomnography, neuropsychological assessment, video swallow study, whole-body fludeoxyglucose–PET (assessing for occult malignancy), and repeat brain MRI were recommended but declined by the patient.

Discussion

Neurological dysfunction punctuated by an episode of subacute encephalitis, followed by spontaneous recovery, is unusual for IgLON5 autoimmunity, which typically (but not always) has an insidious onset and course without signs of CNS inflammation.¹ IgLON5 autoimmunity is known to be characterized by prominent disorders of sleep (parasomnias and sleep-disordered breathing), movement (chorea, ataxia, myoclonus, dystonia, and parkinsonism),

brainstem dysfunction (gait instability, dysphagia, dysarthria, and oculomotor abnormalities), neuropsychiatric abnormalities, and dysautonomia.^{1,2,4} Other recent reports have described milder or more limited phenotypes, including isolated dysphagia⁵ and less pronounced sleep disorders.³

Although our patient had prominent encephalitis from which he recovered, he also had some subtle symptoms before and after the time frame of his subacute illness, supportive of the commonly described features of IgLON5 autoimmunity. In particular, he endorsed mild sleep, gait, bulbar/pseudobulbar, and cognitive complaints months after his encephalitic illness, although these did not manifest as abnormalities on neurologic examination and did not progress over 1 year of follow-up.

This patient had generic clues supportive of autoimmune encephalitis, including subacute onset of neuropsychiatric, gastrointestinal, and urinary symptoms, CSF pleocytosis, and subtle hypothalamic MRI abnormalities. Of note, the initial MRI findings of T2 hyperintensities in the hypothalamus in part paralleled previously reported autopsy findings of 3-repeat and 4-repeat hyperphosphorylated tau preferentially deposited in the hypothalamus, hippocampi, and brainstem tegmentum.⁶ Based on the radiologic findings in our patient, we speculate that tau deposition may be an end product of regional inflammation in IgLON5 autoimmunity.

Limitations of this report include the short duration of clinical follow-up and the patient's preference not to pursue ancillary testing, including polysomnography, further neuroimaging, and human leukocyte antigen typing, which may have elucidated additional features. Although the lack of formal sleep evaluation is a limitation, the mild, nonspecific features and lack of relentless progression make it unlikely that the patient's chronic insomnia was the herald symptom of IgLON5 autoimmunity. In addition, viral encephalitis cannot be ruled out as a cause of encephalitis, although multiple negative PCR test results and clinical deterioration on antiviral therapy argue against this.

We considered other reasons for encountering IgLON5 antibody in this patient. Incidental paraneoplastic antibody testing occasionally can be ascribed to the presence or history of cancer in patients without neurologic symptoms. However, IgLON5 antibody does not have known paraneoplastic significance. The argument that the IgLON5 antibody is a non-specific "epiphenomenon" is weakened by the rarity of the finding (30 cases in 20 years in our laboratory), the consistent and unique neuropathology, and the fact that occasional patients meaningfully improve with immunotherapy.^{3,6,7}

This report, among others, argues for a broadened perspective on the phenotypic scope of IgLON5 autoimmunity, particularly early in the disease course where limited or unusual presentations may occur.
