(Received 19 August 2008; accepted 5 March 2009)

Abstract – *Bartonella rochalimae* was first isolated from the blood of a human who traveled to Peru and was exposed to multiple insect bites. Foxes and dogs are likely natural reservoirs for this bacterium. We report the results of experimental inoculation of two dogs, five cats and six guinea pigs with the only human isolate of this new *Bartonella* species. Both dogs became bacteremic for 5–7 weeks, with a peak of 10^3 – 10^4 colony forming units (CFU)/mL blood. Three cats had low bacteremia levels (< 200 CFU/mL) of 6–8 weeks' duration. One cat that remained seronegative had two bacterial colonies isolated at a single culture time point. A fifth cat never became bacteremic, but seroconverted. None of the guinea pigs became bacteremic, but five seroconverted. These results suggest that dogs could be a reservoir of this strain of *B. rochalimae*, in contrast to cats and guinea pigs.

***Bartonella rochalimae* / dogs / cats / guinea pigs / zoonosis**

1. INTRODUCTION

Bartonella infection was first identified in dogs in 1993, when a novel *Bartonella* subspecies, *B. vinsonii* subsp. *berkhoffii* (*B. v. berkhoffii*), was isolated from a dog with vegetative valvular endocarditis [3]. In the subsequent ten years after recognition of this organism in domestic dogs, six other species of *Bartonella*

were identified in dogs, in association with various clinical manifestations [6]. To date, only two studies have been published on experimental infection of dogs with *Bartonella*, both of which investigated the immunological response and natural history of infection with *B. v. berkhoffii* in dogs [18, 19]. Blood culture and polymerase chain reaction (PCR) of DNA extracted from blood or tissue suggested the establishment of chronic infection despite substantial production of *B. v. berkhoffii*-specific

* Corresponding author: bbchomel@ucdavis.edu

antibodies in both studies. In one of these studies, all six *B. v. berkhoffii* inoculated dogs seroconverted by day 7 post inoculation (PI) using an indirect immunofluorescence antibody (IFA) assay, and all had elevated antibody titers ($\geq 1:64$) for more than 100 days PI [19].

Bartonella rochalimae was first isolated from the blood of a human patient who presented with fever, rash, and splenomegaly after traveling to Peru where she received multiple insect bites [9]. Previously described as *Bartonella clarridgeiae*-like, this zoonotic *Bartonella* species has also been isolated from domestic dogs, gray foxes, raccoons and coyotes in California [11, 12]. Sequential infection with *B. v. berkhoffii* followed by *B. rochalimae* has been observed in a naturally infected gray fox, suggesting a lack of cross-protection between these *Bartonella* species [11]. *B. rochalimae* DNA (originally described as a *B. clarridgeiae*-like species) was also detected in one dog with endocarditis [12, 17]. Because exposure to *B. rochalimae* likely occurred when the American woman tourist was traveling in Peru, we sought to identify which of the domestic animals usually present in traditional rural Peruvian households, i.e. dogs, cats and guinea pigs, could serve as a permissive reservoir host for *B. rochalimae*, using experimental inoculation of animals with the only human isolate available worldwide [9]. Even though the American tourist denied exposure to cats during her trip to Peru [9], and pet cats are not as common as dogs in traditional rural Peruvian households, it was nevertheless important to investigate the susceptibility of cats to this human strain, because *B. rochalimae* is most closely related genetically to *B. clarridgeiae*, a species for which cats are the natural reservoir [6]. Finally, because guinea pigs (*Cavia porcellus*) are commonly raised indoors, roaming free in Peruvian rural households [7, 8], we inoculated guinea pigs to investigate their role as a potential reservoir of *B. rochalimae*. Furthermore, guinea pigs are commonly infested by *Pulex simulans* fleas that will feed readily on humans, and a *Bartonella* species nearly identical to the human isolate of *B. rochalimae* [9] was identified in a *Pulex* flea collected on a human in Cuzco, Peru, based on the sequence

of a fragment of the intergenic spacer region (ITS) [20]. Since then, *B. clarridgeiae*-like/*B. rochalimae* DNA has also been detected in rodent fleas from Egypt [16], China [14] and the USA [1], and has been isolated from field mice from Slovenia [13] and a brown rat (*Rattus norvegicus*) from Taiwan [15], suggesting a role for rodents as reservoirs of *B. rochalimae*. We hypothesized that dogs are more likely to express higher bacteremia levels over a longer period of time than cats when inoculated with the human strain, based on previous experimental infections using a strain isolated from a wild carnivore. Because rodents could harbor *B. rochalimae* or *B. rochalimae*-like bacteria, we hypothesized that guinea-pigs are a potential reservoir for *B. rochalimae*.

Our objectives were to evaluate the susceptibility of cats and guinea-pigs to the unique human isolate of *B. rochalimae* and confirm that dogs, which have been shown to be naturally infected with *B. rochalimae* [11], represent a permissive host for infection with this human isolate. We also sought to confirm a lack of cross-protection between *B. v. berkhoffii* and *B. rochalimae*, as observed in natural infections in wild carnivores. We studied experimental infection with the only human *B. rochalimae* strain in two dogs (one dog had been inoculated previously with *B. v. berkhoffii* and the other dog had no prior exposure to *Bartonella*), five cats, and six guinea pigs. We determined duration of *B. rochalimae* bacteremia, antibody kinetics, and serological cross-reactivity with other *Bartonella* antigens for this study; these parameters have not been examined previously for *B. rochalimae* infection in domestic dogs and cats.

2. MATERIALS AND METHODS

2.1. Animals

Two mongrel male dogs (approximately 3 and 6 years old) that were seronegative and culture negative for *Bartonella* were obtained through the Center for Laboratory Animal Science, University of California, Davis, USA (UCD) for the study. Five 13-month-old neutered male cats that were seronegative and culture

negative for *Bartonella* were obtained from the Feline Research Colony at UCD for the study. Six adult guinea pigs (three males and three females) shown to be blood culture negative and seronegative for *Bartonella* spp. were obtained from the Animal Science Department, UCD. All animals were raised in a flea and tick free environment, the dogs and guinea pigs having been used in other experiments prior to this study. None of these animals had been previously used in experimental infections with animal or human pathogens. The dogs, cats and guinea pigs were maintained in accordance with guidelines of the Institutional Animal Care and Use Committee (IACUC) and were examined by a veterinarian at least once to twice a week throughout the study period.

2.2. Experimental design and bacterial culture

For the two dogs, *B. v. berkhoffii* (ATCC # 51672) or *B. rochalimae* (Human strain: ATCC #BAA-1498) were plated onto 5% rabbit blood agar and incubated at 35 °C for 4–5 days. The harvested colonies were suspended into sterile saline and a total of 0.5 mL was inoculated intradermally in 3 to 5 sites near the shoulder blade, as previously described [2]. Prior to inoculation with *B. rochalimae*, Dog 1 was inoculated with 2.4×10^9 colony forming units (CFU)/mL of *B. v. berkhoffii* and blood samples collected twice a week during the first 4 weeks and then weekly for the two following months. After inoculation with *B. rochalimae*, dogs were bled at least twice a week for the first 5 weeks following inoculation and then once weekly thereafter. All blood samples (500 µL to 1 mL of blood per animal) were cultured on heart infusion agar containing 5% rabbit blood and incubated in 5% CO₂ at 35 °C for up to 4 weeks [4, 5]. After Dog 1 had been culture-negative for *B. v. berkhoffii* for one month, both Dog 1 and Dog 2 were inoculated with 3.5×10^8 CFU/mL of *B. rochalimae*. The two dogs were then followed using blood culture and IFA for three months. Isolates from both dogs were confirmed to be *B. rochalimae* (and not *B. v. berkhoffii*) by PCR-RFLP [12] for the first positive blood culture after inoculation with *B. rochalimae*, and randomly thereafter for Dog 1.

The cats were inoculated with a total of 0.5 mL by the intradermal route in 3 to 4 different sites behind the shoulder blade of a 1.7×10^8 CFU/mL suspension of *B. rochalimae* (Human strain: ATCC #BAA-1498) and clinically monitored daily for the first week. Cats were bled once a week for 15 weeks. Blood culture and serology testing were performed as

previously described [23], and the first positive blood culture confirmed to be *B. rochalimae* by PCR-RFLP.

The six guinea pigs were experimentally inoculated with a total of 0.4 to 0.5 mL by intradermal route (in 3 to 4 different sites on the back) with a 6.1×10^8 CFU/mL suspension of *B. rochalimae* and monitored daily for the first week. A blood sample (0.1 to 0.2 mL) was collected aseptically by intravenous puncture (saphenous vein) every week for 8 weeks. Blood culture and serology testing were performed as previously described [23]. Because of the low volume of whole blood collected, only 25 to 100 µL of whole blood from each guinea pig was plated onto 5% rabbit blood agar.

2.3. Serology

For serological testing of the two dogs, only samples collected at weekly intervals were tested by IFA for antibodies against *B. v. berkhoffii*, *B. clarridgeiae*, *B. rochalimae*, and *B. henselae*, to examine antibody response and cross-reactivity. All IFA slides were prepared the same way by infecting Vero cells with the various strains, as previously described [11]. Cats and guinea pigs were only tested for presence of antibodies against *B. rochalimae* by IFA and a titer $\geq 1:64$ was considered positive. For the guinea-pig samples, we used a goat anti-guinea pig conjugate at 1:100 dilution (Kirkegaard and Pery Laboratories (KPL), Gaithersburg, MD 20879, USA).

3. RESULTS

No physical or clinical abnormalities, except for a small focus of inflammation (redness, swelling) at the inoculation site, were observed in the dogs during the study. None of the cats or guinea pigs presented any abnormal clinical signs during the course of the study.

After inoculation with *B. v. berkhoffii*, Dog 1 developed a positive blood culture by day 17 PI and remained culture positive through day 59 PI. The mean level of bacteremia over these 43 days was 2×10^2 CFU/mL. Initial reciprocal IFA titers against *B. v. berkhoffii* were $< 1:16$, rose to 1:64 by day 9 PI and peaked at 1:256 within 2 weeks of the first positive blood culture (Fig. 1). The *B. v. berkhoffii* antibody titer was $< 1:16$ at the time of

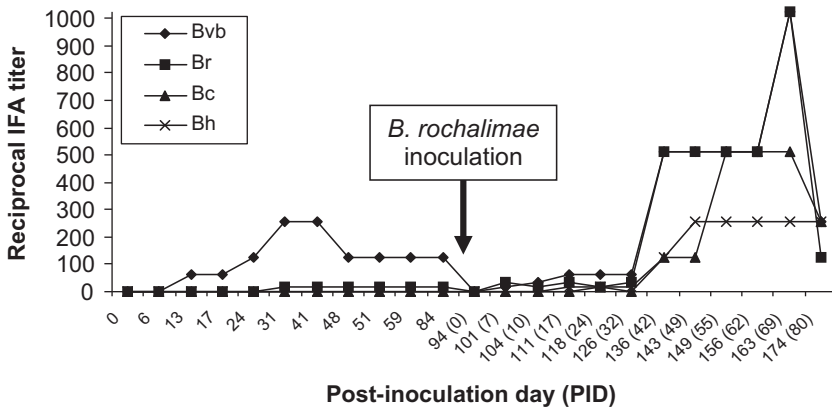

Figure 1. IgG antibody response in Dog 1 experimentally infected with *B. v. berkhoffii* and challenged with *B. rochalimae*. The dog was tested by IFA for antibodies against *B. v. berkhoffii* (Bvb), *B. rochalimae* (Br), *B. clarridgeiae* (Bc), and *B. henselae* (Bh). The dog was inoculated with a strain of *B. rochalimae* on *B. v. berkhoffii* PI day 94 (day 0 in parentheses on X axis).

inoculation with *B. rochalimae*, 94 days after the first inoculation with *B. v. berkhoffii*. There was no cross reactivity of anti-*B. v. berkhoffii* antibodies with antigens from other *Bartonella* species by IFA, and titers for *B. clarridgeiae*, *B. rochalimae*, and *B. henselae* remained $\leq 1:16$ (Fig. 1). Following inoculation with *B. rochalimae*, Dog 1 became blood culture positive for *B. rochalimae* (speciation confirmed by PCR-RFLP) at day 24 PI (118 days after inoculation with *B. v. berkhoffii*) and remained bacteremic through day 62 PI (Tab. I). A substantial increase in *Bartonella* IFA antibody titers was not observed until 18 days (day 42 PI) after *B. rochalimae* bacteremia was first observed. *B. rochalimae* and *B. v. berkhoffii* titers both peaked at 1:1024 on day 163 PI and demonstrated substantial cross reactivity with the other *Bartonella* antigens tested (Fig. 1). Dog 2, inoculated only with *B. rochalimae*, had a positive blood culture by day 10 PI and remained culture positive through day 80 PI. Bacteremia peaked at day 17 PI (5.5×10^4 CFU/mL) and decreased through day 42 PI. There was one negative culture on day 49 PI, followed by a second and lower increase in bacteremia with a peak of 5.1×10^2 CFU/mL on day 69 PI. Detectable levels of bacteremia ranged from 8 CFU/mL

to 5.1×10^3 CFU/mL in Dog 1 and from 1 CFU/mL to 5.5×10^4 CFU/mL in Dog 2. Mean level of bacteremia was 7.6×10^2 CFU/mL for Dog 1 and 8×10^3 CFU/mL for Dog 2. *B. rochalimae* IFA antibody titers ($> 1:16$) were not observed in Dog 2 until day 24 PI, 14 days after *Bartonella* infection was detected by blood culture and titers increased rapidly and peaked at 1:1024 on day 32 PI. Moderate to low seroreactivity to *B. clarridgeiae* and *B. henselae* antigens was also observed in this dog, whereas *B. v. berkhoffii* antibody titers remained $\leq 1:32$ (Fig. 2).

Bacteremia was detected in 4 of the 5 cats. In three cats, bacteremia was detected at week 3 PI, peaked between weeks 6 and 7, and resolved by weeks 8 to 10. A fourth cat had a transient and low level bacteremia (2 CFU/mL) on week 12, and the fifth cat remained culture negative throughout the 15-week study period. Overall, the level of bacteremia was low (less than 10 CFU/mL for one cat, less than 50 CFU/mL for two cats, and less than 200 CFU/mL for one cat) and at least 10–100 times less than in the two dogs. Four of the five cats seroconverted (Tab. II). Three cats were seropositive for *B. rochalimae* 3 weeks PI, with titers ranging from 1:64 to 1:512 until the end of the study (week 15), and one cat seroconverted

IgG seroconversion (titer \geq 1:64) on day 19 PI. Four of the 6 animals were seropositive by day 32 PI (range 1:64 to 1:128). At the end of the study (day 53 PI), all but one guinea pig had seroconverted (titer range: 1:64 to 1:256).

4. DISCUSSION

The present study, although limited in size, demonstrates a difference in susceptibility among domestic dogs, cats, and guinea pigs to experimental infection with a human isolate of *B. rochalimae*. To date, isolates of this new *Bartonella* species have been cultured from mammals in the new world, including from a human who traveled to South America [9], and from gray foxes, raccoons, coyotes and domestic dogs in California [11, 12]. In addition, *B. rochalimae* has been cultured from a red fox (*Vulpes vulpes*) from France¹ and a strain closely related to *B. rochalimae* was recently isolated from a rat in Taiwan [15].

In our study, inoculation of two dogs with the human *B. rochalimae* isolate led to a successful infection, with bacteremia lasting 5 to 7 weeks and a peak bacteremia reaching 10^3 to 10^4 CFU/mL. This level of bacteremia is similar to the level observed in two dogs experimentally infected with a *B. rochalimae* strain isolated from a Californian coyote², and dogs experimentally inoculated with *B. v. berkhoffii*, another *Bartonella* sp. that has been isolated from canids [18, 19]. In our investigation, prior infection with *B. v. berkhoffii* in one dog was not protective against infection with *B. rochalimae*, which is consistent with observations in a naturally infected gray fox from California [11], and suggests that co-infection with these two *Bartonella* species could occur in domestic dogs. Similarly, in experimentally infected cats, a lack of cross-protection has been demonstrated between *B. henselae* and *B. clarridgeiae* [22]. Following inoculation with *B. v. berkhoffii*, Dog 1 developed only moderately elevated (1:256) IFA titers against *B. v. berkhoffii* but not against the other antigens

¹ Henn et al., unpublished data.

² Chomel et al., unpublished data.

tested, and titers reverted to negative ($\leq 1:16$) within 35 days of the last positive blood culture. In contrast, dogs experimentally inoculated with *B. v. berkhoffii* in another study had *B. v. berkhoffii* antibody titers that remained elevated ($\geq 1:64$) for more than 100 days PI [19]. The low and rapid decline in antibody titers in Dog 1 could be a result of the failure of *B. v. berkhoffii* to establish persistent infection. In both dogs, a detectable *B. rochalimae* IgG antibody response appeared 2–3 weeks following the appearance of the first positive blood culture. Dog 1, previously exposed to *B. v. berkhoffii*, had IFA titers of ≥ 512 against all four *Bartonella* antigens, whereas for Dog 2 high IFA titers were only observed for *B. rochalimae* antigens. Previous studies have noted a correlation between high IFA titers and seroreactivity to multiple *Bartonella* species [10, 21]. These limited results suggest that infection or re-infection with multiple species of *Bartonella* could substantially increase the serological cross reactivity between *Bartonella* species. As co-infection with more than one *Bartonella* species has been documented in several animal species, including dogs and humans, examination of cross-reactivity in naturally-exposed animals becomes more challenging and would require immuno-absorption studies.

In contrast to observations in experimentally infected dogs, the experimentally infected cats did not show high levels of bacteremia. The peak bacteremia was above 100 CFU/mL in only one of the five cats, and was at least 10 to 100 fold lower than in experimentally infected dogs. Levels of bacteremia were also much lower than in cats experimentally infected with *B. henselae* or *B. clarridgeiae* [22–24]. Based on this small study, cats do not appear to be highly susceptible to the human isolate of *B. rochalimae* and are unlikely to constitute a natural reservoir for this human strain. There are no reports in the published literature of cats infected with *B. rochalimae* and other *B. clarridgeiae*-like spp. On the other hand, despite recent reports of the presence of *B. clarridgeiae*-like/*B. rochalimae* strains in rodents and rodent fleas, we were unable to detect infection with *B. rochalimae* in the six

experimentally inoculated guinea pigs, despite a high inoculum dose (10^8 CFU/mL). The lack of detection could be related to the low volume of blood cultured and/or to a very low level of bacteremia. As the guinea-pigs were bled only once a week, detection of a very short term bacteremia could have been missed. Although we did not detect *B. rochalimae* bacteremia, the guinea pigs did develop a detectable humoral immune response to the experimental infection. Based on our data, guinea pigs do not appear to constitute a permissive reservoir for *B. rochalimae*. However, field studies should be conducted to confirm our results.

In conclusion, we sought to identify potential reservoir species from which the human strain of *B. rochalimae* could be acquired. We focused on animal species commonly found in the domestic environment to which the traveler could have been exposed in Peru: dogs and guinea pigs. We also included cats, because they are the natural reservoir of *B. clarridgeiae*, the *Bartonella* species that is closest phylogenetically to *B. rochalimae*. The dog appears to be the most permissive host of cats, dogs and guinea pigs, which is consistent with the isolation of *B. rochalimae* strains from wildlife canids. Further elucidation of reservoir hosts, including other rodent species, such as rats, as well as arthropod vectors, especially *Pulex* spp. fleas, for this new *Bartonella* species will be important in preventing infection of humans, and domestic and peri-domestic animals.
