**Abstract.** Morphological variations in the left atrial appendage (LAA) are associated with different levels of ischemic stroke risk for patients with atrial fibrillation (AF). Studying LAA morphology can elucidate mechanisms behind this association and lead to the development of advanced stroke risk stratification tools. However, current categorical descriptions of LAA morphologies are qualitative and inconsistent across studies, which impedes advancements in our understanding of stroke pathogenesis in AF. To mitigate these issues, we introduce a quantitative pipeline that combines elastic shape analysis with unsupervised learning for the categorization of LAA morphology in AF patients. As part of our pipeline, we compute pairwise *elastic distances* between LAA meshes from a cohort of 20 AF patients, and leverage these distances to cluster our shape data. We demonstrate that our method clusters LAA morphologies based on distinctive shape features, overcoming the innate inconsistencies of current LAA categorization systems, and paving the way for improved stroke risk metrics using objective LAA shape groups.

**Keywords:** elastic shape analysis · computational anatomy · left atrial appendage · ischemic stroke · atrial fibrillation.

## 1 Introduction

Atrial fibrillation (AF) is the most common cardiac arrhythmia, characterized by irregular contractions of the atrial chambers [1]. It represents an emerging global health crisis, affecting 2–3% of individuals worldwide, with its prevalence expected to increase 2.5-fold in the next 40 years [2]. This rhythm disorder is associated with blood stagnation and clot formation in the left atrial appendage (LAA) – a tubular pouch attached to the main body of the left atrium [3]. A devastating complication of AF occurs when clots detach from the LAA and travel to the brain, causing vessel blockage and leading to ischemic stroke [4]. The risk of stroke in AF patients is five times that of a healthy individual [5].

Numerous studies have shown that LAA morphology is correlated with different levels of ischemic stroke risk [6,7,8,9]. Despite this evidence, the ubiquitously employed stroke risk stratification metrics for AF patients overlook geometric considerations of the LAA [10]. Furthermore, these metrics often inaccurately determine which patients should receive oral anticoagulants, which can cause severe side effects such as internal bleeding and intracranial hemorrhage [10,11,12,13,14,15,16]. Additionally, in current LAA shape classification systems, the “chicken-wing” appendage is known to exhibit lower stroke prevalence compared to other categories (e.g., windsock, cauliflower, cactus) [9,17]. However, the high inter-observer variability in these qualitative classification systems has led to inconsistent definitions of LAA morphology categories across different studies and patient populations [18]. Consequently, mixed conclusions have been documented regarding the association between LAA morphologies and ischemic stroke risk, hindering the incorporation of LAA shape information into stroke risk assessments [19]. Therefore, an objective framework for LAA shape categorization is imperative.

Some studies quantify LAA shape using simple metrics and functional data [20,21,7], but only a few studies have used detailed shape analysis approaches. Slipsager et al. developed a framework for the statistical shape analysis and clustering of LAA geometries based on non-rigid volumetric registration of signed distance fields, and Juhl et al. further extended this work [22,23]. These methods face limitations as they require point-to-point correspondences between LAA meshes (i.e., parametrized 3D surfaces) for statistical shape analysis.

In this paper, we propose a novel computational pipeline for LAA morphology categorization which combines automated atrial segmentation, mesh generation, *elastic distance* computations, and hierarchical clustering. For 3D LAA meshes from 20 AF patients, we compute and leverage pairwise elastic distances to (a): quantify the similarity between pairs of shapes by calculating the Riemannian energy required to deform one of them into the other, and (b): cluster the meshes into distinct categories based on these shape similarities. Our pipeline has the ability to operate on unparametrized surfaces, which circumvents the requirement of point-to-point correspondences between LAA geometries, and renders the pipeline readily implementable in clinical workflows.

## 2 Methods

In what follows, we describe our LAA data, provide theoretical background on elastic shape analysis (ESA), and detail our computational approach for clustering the LAA geometries.

### 2.1 Data Description and Preparation

A dataset of 20 de-identified contrast-enhanced computed tomography (CT) scans of AF patients was used in this study. We adapted a deep learning model to automate LA segmentations on the CT scans [24]. The model has a cascade

**Fig. 1.** Schematic summary of the pre-processing pipeline: From 3D CT images, we automatically segment the LA using a deep learning approach, and generate a triangulated 3D mesh. Then the LAA (red) is clipped from the LA body (blue) and re-meshed.

structure, where a region of interest is first cropped and followed by a convolutional neural network (CNN) that performs segmentation on the cropped area. All CNN-segmented scans were examined manually by an imaging expert \*\*\*\*\* for quality check. From the LA segmentations, we isolated the LAA from the LA chamber using *Paraview*'s clip tool, such that the ostium was orthogonal to the initial protrusion of the appendage from the main body of the chamber, based on the LAA segmentation approach in [25]. We then re-meshed the clipped LAA to yield the fully pre-processed geometry for shape analysis, see Figure 1.

## 2.2 Elastic Shape Analysis

The “shapes” of interest to us in this article are LAA meshes, which we model mathematically (from a continuous viewpoint) as surfaces immersed in  $\mathbb{R}^3$ . As such, our approach for LAA shape comparison and categorization relies fundamentally on a quantitative measure of similarity (i.e., a distance) between surfaces. The framework of Riemannian shape analysis is particularly well-suited for defining such notions, whereby at a high level, distances between pairs of geometric objects (such as LAA meshes) correspond to the minimal amount of ‘energy’ required to morph one of the objects into the other via a combination of geometric transformations such as bending and stretching [26,27,28,29]. In what follows, we outline the theoretical underpinnings of this framework.

Let us start by defining a *parametrized immersed surface* in  $\mathbb{R}^3$ , which refers to a smooth mapping  $q \in C^\infty(M, \mathbb{R}^3)$ , whose differential  $dq$  is injective at every point of the parameter space  $M$ , which is a 2-dimensional compact manifold (possibly with boundary) whose local coordinates are denoted by  $(u, v) \in \mathbb{R}^2$ . For example,  $M$  can be a compact domain of  $\mathbb{R}^2$  if one is working with open LAA meshes, or the sphere  $\mathbb{S}^2$  in the setting of closed LAA meshes. The set of all parametrized surfaces, denoted by  $\mathcal{I}$ , is itself an infinite-dimensional manifold, where the tangent space at any  $q \in \mathcal{I}$ , denoted  $T_q\mathcal{I}$ , is given by  $C^\infty(M, \mathbb{R}^3)$ . Any tangent vector  $h \in T_q\mathcal{I}$  can be thought of as a vector field along the surface  $q$ .

The key ingredient in Riemannian shape analysis is to equip the manifold  $\mathcal{I}$  with a Riemannian metric  $G$ , which in our case refers to a family of inner products  $G_q : T_q\mathcal{I} \times T_q\mathcal{I} \rightarrow \mathbb{R}$  that varies smoothly with respect to  $q \in \mathcal{I}$ .

Indeed, any Riemannian metric  $G$  on  $\mathcal{I}$  induces a (pseudo) distance on this space, which is given for any two parametrized surfaces  $q_0, q_1 \in \mathcal{I}$  by

$$d_G(q_0, q_1)^2 = \inf_{q(\cdot) \in \mathcal{P}_{q_0}^{q_1}} \int_0^1 G_{q(t)}(\partial_t q(t), \partial_t q(t)) dt, \quad (1)$$

where the infimum is taken over the space of all paths of immersed surfaces connecting  $q_0$  and  $q_1$ , which we write as

$$\mathcal{P}_{q_0}^{q_1} := \{q(\cdot) \in C^\infty([0, 1], \mathcal{I}) : q(0) = q_0, q(1) = q_1\}, \quad (2)$$

with  $\partial_t q(t)$  denoting the derivative of this path with respect to time  $t$ . We refer to the minimization problem in (1) as the *parametrized matching problem*, where  $q_0$  and  $q_1$  are called the *source* and *target* surfaces respectively, with  $d_G$  being known as the *geodesic distance* between  $q_0$  and  $q_1$ , and where minimizing paths  $q(\cdot) \in \mathcal{P}_{q_0}^{q_1}$  (if they exist) are termed *geodesics*. The functional being minimized in (1) is called the *Riemannian energy* of the path  $q(\cdot)$ , and thus, geodesics can be interpreted as optimal deformations of minimal ‘energy’ between  $q_0$  and  $q_1$ . In a Riemannian setting, geodesics and distances obtained via (1) form the basis of frameworks for the comparison and statistical shape analysis of surfaces, see [28].

**Fig. 2.** Example computation of the geodesic (optimal deformation) between a source LAA surface ( $q_0$ ) and target LAA surface ( $q_1$ ) to obtain the geodesic distance  $d_G(q_0, q_1)$ .

Nevertheless, we need to look beyond the setting of parametrized surfaces, i.e., geometric data with known point-to-point correspondences. Indeed, our goal is to develop a method for the comparison of LAA morphologies on datasets of unregistered LAA meshes, independently of how they are parametrized (or sampled/discretized). To this end, we introduce the *reparametrization group*  $\mathcal{D}$ , i.e., the group of all diffeomorphisms (smooth and bijective maps  $\varphi \in C^\infty$ ) of the parameter space  $M$ . For any surface  $q \in \mathcal{I}$  and  $\varphi \in \mathcal{D}$ , we say that  $q \circ \varphi \in \mathcal{I}$  is a *reparametrization* of  $q$  by  $\varphi$ . The discrete analogue of a reparametrization of a surface is a re-meshing of a discretized (e.g. triangulated) 3D mesh.

Since we seek geodesic distances between shapes regardless of how they are parametrized, let us introduce the *shape space of unparametrized surfaces*, defined as the quotient space of parametrized surfaces modulo the reparametrization group  $\mathcal{S} = \mathcal{I}/\mathcal{D}$ , which consists of equivalence classes  $[q] = \{q \circ \varphi | \varphi \in \mathcal{D}\}$  comprised of all reparametrizations of a given surface  $q \in \mathcal{I}$ . To obtain a distance

on the shape space, we require a Riemannian metric  $G$  that is invariant under the action of the aforementioned reparametrization group  $\mathcal{D}$ , i.e., we require

$$G_q(h, k) = G_{q \circ \varphi}(h \circ \varphi, k \circ \varphi) \quad (3)$$

for all  $q \in \mathcal{I}$ ,  $h, k \in T_q\mathcal{I}$  and  $\varphi \in \mathcal{D}$ . The field of *elastic shape analysis* (ESA) is a particularly powerful source of Riemannian metrics satisfying the reparametrization-invariance property above [26,27].

In this paper, we shall focus on *second-order Riemannian Sobolev metrics* ( $H^2$ -metrics), which have been shown to possess several desirable properties including the reparametrization-invariance property in (3), and which have successfully been used in applications with unregistered 3D geometric data [26,28,30,31]. For all  $q \in \mathcal{I}$  and  $h, k \in T_q\mathcal{I}$ , the family of  $H^2$ -metrics is defined as:

$$\begin{aligned} G_q(h, k) = \int_M & \left( a_0 \langle h, k \rangle + a_1 g_q^{-1}(dh_m, dk_m) \right. \\ & + b_1 g_q^{-1}(dh_+, dk_+) + c_1 g_q^{-1}(dh_\perp, dk_\perp) \\ & \left. + d_1 g_q^{-1}(dh_0, dk_0) + a_2 \langle \Delta_q h, \Delta_q k \rangle \right) \text{vol}_q, \end{aligned} \quad (4)$$

where  $a_0, a_1, b_1, c_1, d_1, a_2$  are non-negative weighting coefficients for the different zeroth, first and second order terms in the metric. In the above,  $dh$  is the vector valued one-form on  $M$  given by the differential of  $h$ , i.e., a map from  $TM$  to  $\mathbb{R}^3$  which can be viewed as a  $3 \times 2$  matrix field on  $M$  (in a given coordinate system). Meanwhile,  $g_q = q^* \langle \cdot, \cdot \rangle$  is the pullback of the Euclidean metric on  $\mathbb{R}^3$ , which can be represented as a  $2 \times 2$  symmetric positive definite matrix field on  $M$ , implying that  $g_q^{-1}(dh, dh) = \text{tr}(dh g_q^{-1} dh^T)$ . Finally, the second-order term involves the Laplacian  $\Delta_q$  induced by  $q$ , which can be written in coordinate-form as  $\Delta_q h = \frac{1}{\sqrt{\det(g_q)}} \partial_u \left( \sqrt{\det(g_q)} g_q^{uv} \partial_v h \right)$ . We note that the first-order term in the metric is split as a result of the orthogonal decomposition of  $dh$  into the sum of  $dh_m, dh_+, dh_\perp$  and  $dh_0$ , where the precise definitions of these terms are given in [28]. The important thing to note about splitting the metric in this way is that the terms weighted by  $a_1, b_1, c_1$  in (4) correspond to shearing, stretching and bending energies induced by the deformation field  $h$  respectively. Therefore, the class of invariant  $H^2$ -metrics provides us with the flexibility to emphasize or penalize different types of deformations when computing geodesics via the selection of the weighting coefficients. This is particularly useful when working LAA meshes, as it allows us to incorporate prior knowledge about LAA geometry when selecting parameters to compute pairwise distances, which helps us obtain meaningful distances for downstream tasks such as clustering.

With a reparametrization-invariant Riemannian metric  $G$  in hand, such as an  $H^2$ -metric from (4), its associated geodesic distance function  $d_G$  given in (1) descends to a distance  $d_S$  on the quotient shape space  $\mathcal{S}$ , which is given for any

$[q_0], [q_1] \in \mathcal{S}$  by:

$$d_{\mathcal{S}}([q_0], [q_1])^2 = \inf_{\varphi \in \mathcal{D}} d_G(q_0, q_1 \circ \varphi)^2 = \inf_{\varphi \in \mathcal{D}} \inf_{q(\cdot) \in \mathcal{P}_{q_0}^{q_1 \circ \varphi}} \int_0^1 G_{q(t)}(\partial_t q(t), \partial_t q(t)) dt. \quad (5)$$

To compute geodesic distances on the shape space, we thus need to solve the *un-parametrized matching problem* above, which involves finding an optimal path of immersions from  $q_0$  (having a fixed parametrization) to an optimal reparametrization of  $q_1$ , i.e., we require an optimal path such that  $q(0) = q_0$  and  $q(1) = q_1 \circ \varphi$ .

In practice, solving (5) numerically is challenging. Indeed, it is relatively straightforward to discretize the  $H^2$ -metric and Riemannian energy functional by considering surfaces discretized as triangulated meshes [28], which allows us to frame the minimization over paths of surfaces as a standard finite-dimensional optimization problem. Yet, the optimization over reparametrizations of  $q_1$  is challenging as the discretization of the diffeomorphism group  $\mathcal{D}$  and its action on surfaces is not straightforward, see [27,32]. This motivates the need for alternative techniques for solving (5). One approach, recently proposed in [28,33], deals indirectly with the minimization over reparametrizations of  $q_1$  by instead introducing a relaxation of the end time constraint  $q(1) \approx q_1 \circ \varphi$  using a *data attachment term*  $\Gamma([q(1)], [q_1])$  that is independent of the parametrizations of either  $q(1)$  or  $q_1$ . Broadly speaking, this approach involves solving the *relaxed matching problem* below:

$$\inf \left\{ \int_0^1 G_{q(t)}(\partial_t q(t), \partial_t q(t)) dt + \lambda \Gamma([q(1)], [q_1]) \right\}, \quad (6)$$

where the minimization occurs over paths of surfaces  $q(\cdot) \in C^\infty([0, 1], \mathcal{I})$  that satisfy the initial constraint  $q(0) = q_0$  *only*, and where  $\Gamma([q(1)], [q_1])$  is a term that measures the discrepancy between the endpoint of the path  $q(1)$  and the true target surface  $q_1$ , with  $\lambda > 0$  being a balancing parameter. In particular, this approach allows us to bypass the optimization over the diffeomorphism group  $\mathcal{D}$ . In this paper, we follow the approach of past works with unregistered surface data [33,28,30] and define  $\Gamma$  specifically as a kernel metric on the space of varifolds. While we omit the technical details behind the construction of these so-called varifold fidelity metrics in this paper for concision, we refer interested readers to the works of [34,35] for further details.

To bring everything together, our approach for computing pairwise distances for the comparison and categorization of LAA morphologies involves discretizing the LAA geometries as triangulated 3D meshes, and solving the relaxed matching problem (6) numerically using the approach of [28], where the Riemannian metric  $G$  is an  $H^2$ -metric (4), and where the data attachment term  $\Gamma$  is the varifold fidelity metric defined in [28]. For clarity, in the results for LAA shape categorization presented in Section 3, and in particular in Figure 3a, the distances we report are estimates  $\tilde{d}_{\mathcal{S}}(q_0, q_1)$  for the true shape distance  $d_{\mathcal{S}}(q_0, q_1)$  between a given pair of LAA meshes  $q_0$  and  $q_1$ , which are given by  $\tilde{d}_{\mathcal{S}}(q_0, q_1) \doteq \int_0^1 G_{q(t)}(\partial_t q(t), \partial_t q(t)) dt$ , where the expression on the right is evaluated at an optimal path of surfaces  $q(\cdot)$  found by solving (6).

### 2.3 Hierarchical Clustering of LAA Geometries

Equipped with elastic distances, we use hierarchical clustering (with Ward’s linkage method) to cluster the LAA geometries. Hierarchical clustering is a method used to group a set of objects into categories (clusters) based on their similarity to each other, which is quantified using a distance metric. This approach is particularly useful for categorizing 3D shapes based on pairwise distances within a high-dimensional manifold [36].

Specifically, given a set of shapes  $\{q_1, \dots, q_n\} \in \mathcal{S}$ , where  $D \in \mathbb{R}^{n \times n}$  is the symmetric matrix whose entries  $D_{ij}$  represent the distance between shape  $q_i$  and  $q_j$  (e.g., elastic distances  $d_{\mathcal{S}}(q_i, q_j)$  computed via (6)), hierarchical clustering operates as follows: Initially, each shape is considered a separate cluster, leading to  $n$  clusters,  $C \doteq \{c_1, \dots, c_n\}$  where  $c_i = \{q_i\}$ . We iteratively merge the closest clusters by identifying  $c_a$  and  $c_b$  that minimize the increase in total within-cluster variance, defined below:

$$\Delta \text{Var}(c_a, c_b) = \text{Var}(c_{new}) - \text{Var}(c_a) - \text{Var}(c_b), \quad (7)$$

where  $\text{Var}(c)$  is defined as the average of the squared distances between each point in a given cluster  $c$  and the cluster’s centroid. At each iteration, the two closest clusters  $c_a$  and  $c_b$  are merged into a new cluster  $c_{new} = c_a \cup c_b$ , and  $C \leftarrow (C \setminus \{c_a, c_b\}) \cup \{c_{new}\}$  is updated accordingly. This process iterates until all shapes are grouped into a desired number of clusters.

### 2.4 Multidimensional Scaling to Visualize Clusters

After clustering, we employ multi-dimensional scaling (MDS) to visualize LAA shape clusters in a lower-dimensional Euclidean space [37]. That is, given a set of LAA shapes  $\{q_1, \dots, q_n\} \in \mathcal{S}$  with corresponding geodesic distance function  $d_{\mathcal{S}}$ , we use MDS to find  $\hat{x}_1, \dots, \hat{x}_n \in \mathbb{R}^m$  (for some  $m \in \mathbb{N}$ ) such that

$$\hat{x}_1, \dots, \hat{x}_n = \underset{y_1, \dots, y_n \in \mathbb{R}^m}{\text{argmin}} \left( \sum_{i \neq j} (d_{\mathcal{S}}(q_i, q_j) - \|y_i - y_j\|)^2 \right)^{\frac{1}{2}}, \quad (8)$$

which yields a mapping of the LAA geometries as points in  $\mathbb{R}^m$ , while preserving relative information about their pairwise distances in the original shape space.

## 3 Results

Figure 3 presents results of our quantitative pipeline for LAA morphology categorization on the cohort of LAA geometries.

**Fig. 3.** (a) Symmetric matrix representing pairwise elastic distances computed for our cohort of 20 LAA geometries described in Section 2.1. (b) Dendrogram illustrating LAA shape clusters obtained via hierarchical clustering, with the threshold (red dashed line) used to separate the geometries into five clusters. (c) MDS plot of the LAA geometries with 10 LAA shapes plotted over their embeddings in 2D Euclidean space. Two LAA meshes from each category are shown and color-matched to clusters in the dendrogram.

The computed elastic distances between all pairs of LAA meshes in the cohort are displayed in the distance matrix in Figure 3a. Each element of the matrix takes approximately 1-3 minutes to compute on a GPU. These distance estimates, obtained via the relaxed matching problem (6), are not a priori symmetric due to the varifold relaxation term. We therefore selected a subset of our LAA meshes and computed  $d_S(q_i, q_j)$  and  $d_S(q_j, q_i)$  for all pairs of meshes  $q_i, q_j$  in this subset. We found the computed distances to be within a round off error of each other (i.e.,  $d_S(q_i, q_j) \approx d_S(q_j, q_i)$ ), and therefore only computed the upper-triangular part of the matrix in Figure 3, before symmetrizing it.

After computing the pairwise distances, we applied hierarchical clustering and MDS to categorize and visualize the LAA clusters based on their geometric similarities, with results shown in Figures 3b and 3c. The dendrogram illustrating the hierarchical clustering results in Figure 3b facilitated the selection of a threshold (the red dashed line) for the identification of five distinct LAA shape clusters. We projected these LAA shape clusters into 2D Euclidean space via MDS in Figure 3c, where we have plotted a subset of 10 representative geometries (two from each cluster) to avoid overcrowding the figure.

The results demonstrate that, even on a modest dataset of 20 LAA geometries, our pipeline can cluster LAA shapes with similar morphology into the same group while separating different shape types into distinct clusters. Notably, the green and white LAA groups could both be identified as “chicken wing” appendages in current qualitative categorization systems. Yet, our method groups them in different clusters, demonstrating that our pipeline can detect subtle shape features not captured by qualitative classifications, thereby enabling the identification of intermediate shape groups between the qualitative categories.

## 4 Discussion

**Advantages of our approach:** Unlike previous studies that necessitate precise point-to-point correspondences for comparing and categorizing LAA shapes, our approach is adapted for unparametrized surfaces, leveraging the relaxed matching approach detailed in (6). Indeed, establishing point correspondences often incurs high computational costs and can yield unsatisfactory results with complex geometric data [22,23]. For instance, Juhl et al. mention that they chose to refine the point correspondence on decoupled LAAs due to the large differences in size and complexity between the LAA and the remaining LA, making it difficult to maintain good correspondences over the entire mesh [23]. Even state-of-the-art methods for finding point correspondences with 3D geometric data, such as the functional maps framework, struggle with fine-grained and intricate geometries, unless a good prior selection of landmarks is provided [38]. By alleviating the need for point correspondences, our approach thus overcomes the computational hurdles often encountered during the registration of complex geometric data such as LAA meshes [22,23,38].

**Limitations:** Some limitations of our work include the computational time required for pairwise distance calculations on large datasets and the complex parameter tuning process for computing elastic distances which could be improved via the supervised learning approach of [39] to predict the elastic distances, and the parameter selection criteria of [40], respectively. We note, however, that these tasks need only be performed once to solidify shape categories.

**Clinical Significance:** Our framework’s compatibility with unparametrized surfaces enables us to work with LAA meshes with diverse vertex counts and discretization schemes with minimal pre-processing, thereby significantly enhancing its flexibility with data that has been acquired or segmented via different techniques and/or with data from different hospitals. This can enable efficient comparison of new LAA shapes to representative or averaged template shapes from *established* clusters. Avenues for future work include establishing clusters on a larger LAA dataset with stroke history information to refine the shape categorization system and identify clusters with higher stroke prevalence. This effort would allow clinicians to objectively compare new LAA geometries—sourced by various imaging acquisition modalities and healthcare centers—into one of the predefined groups or measure their distance from high-risk groups. This could lead to new metrics for stroke likelihood in AF patients and improve clinical decision-making regarding the administration of preventative medications (such as anticoagulants) with severe side effects [11].

**Conclusion:** Our integrated approach of performing hierarchical clustering followed by MDS on the elastic distances provides a comprehensive framework for categorizing and visualizing the complex geometric variations of LAA shapes, with applications towards improved stroke risk management in AF patients.
