

Since January 2020 Elsevier has created a COVID-19 resource centre with free information in English and Mandarin on the novel coronavirus COVID-19. The COVID-19 resource centre is hosted on Elsevier Connect, the company's public news and information website.

Elsevier hereby grants permission to make all its COVID-19-related research that is available on the COVID-19 resource centre - including this research content - immediately available in PubMed Central and other publicly funded repositories, such as the WHO COVID database with rights for unrestricted research re-use and analyses in any form or by any means with acknowledgement of the original source. These permissions are granted for free by Elsevier for as long as the COVID-19 resource centre remains active.

El hecho fisiopatológico que subyace a la presencia de hipoxemia en el SPO es el efecto *shunt*¹. Las causas asociadas al SPO se clasifican en etiologías intracardiacas, extracardiacas (pulmonares) y en un tercer grupo heterogéneo¹. En las enfermedades pulmonares, el *shunt* puede establecerse bien por la mezcla de sangre arterial y venosa (como en las fistulas arteriovenosas), bien por una alteración grave de la relación V/Q², como sucede en algunas enfermedades parenquimatosas. Por efecto de la gravedad, el flujo sanguíneo se incrementa hacia las bases pulmonares mientras que disminuye la presión de perfusión en las regiones apicales (efecto *espacio muerto* en ápex). Esta redistribución vascular contribuye a incrementar las diferencias en la relación V/Q, las cuales son especialmente notables en bipedestación³. Así, se ha descrito el desarrollo de SPO asociado a enfisema, enfermedades intersticiales y consolidaciones especialmente cuando involucran al parénquima basal⁴. Dentro de esta definición, también tendrían cabida las alteraciones pulmonares propias del síndrome respiratorio agudo del adulto (SDRA).

Por otro lado, los datos analizados hasta el momento sugieren que el nuevo coronavirus tiene especial tropismo por el endotelio vascular. El SARS-CoV-2 inicia la infección celular mediante su unión al receptor de la enzima convertidora de angiotensina II, un receptor ampliamente distribuido en el organismo, incluyendo el endotelio. Algunas series de autopsias han demostrado inclusiones virales en las células endoteliales con acúmulos de células inflamatorias, hallazgos sugestivos de endotelitis⁵. Así, la activación endotelial inducida por el virus puede dar lugar tanto a fenómenos trombóticos como a una marcada vasodilatación. A nivel pulmonar, la vasodilatación y la disfunción endotelial agravan el efecto *shunt* observado en algunos pacientes⁶. En una revisión de manifestaciones radiológicas por COVID-19 detectadas por TC, se observó como hallazgo frecuente la dilatación de vasos pulmonares, especialmente aquellos más próximos o dentro de áreas de vidrio deslustrado⁷. Dicho fenómeno parece estar en relación directa con la producción de mediadores inflamatorios, en especial IL-1 e IL-6, citoquinas que han demostrado tener un potente efecto vasodilatador *in vivo*⁸. La vasodilatación inducida tanto por los mediadores inflamatorios como por la lesión endotelial vírica directa, podría ser la causa del efecto *shunt*.

El interés del presente caso radica, no solo en la infrecuencia del SPO, sino en su asociación con la infección por SARS-CoV-2. Existe reporte de casos de SPO asociados a agentes infecciosos durante el periodo de convalecencia tras un episodio de SDRA por *Pseudomonas aeruginosa*⁹ y neumonías por *Pneumocystis jirovecii* y citomegalovirus¹⁰, aunque también se ha descrito en SDRA asociado a agentes no infecciosos como el síndrome antisintetasa¹¹. Sin embargo, no existe bibliografía hasta el momento que relacione el SPO con las alteraciones anatomicofuncionales propias de una neumonía grave por COVID-19.

Twice Lucky: Elderly Patient Surviving Both COVID-19 and Serendipitous Lung Carcinoma

Sobrevivir a una infección COVID-19 conduce a curar un carcinoma pulmonar

Dear Editor:

As of 4 June 2020, the number of confirmed cases of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) in Spain is 240,326, many of whom have developed the coronavirus disease 2019 (COVID-19).¹ Despite the high number of deaths (around 27,000), more than 120,000 patients have been cured.¹ Once the outbreak is over, the new situation we face is dealing with non-related COVID pathologies in patients diagnosed with COVID-19 or who have recently overcome the disease.

A 78-year old former smoker (cumulative cigarette smoking more than 30 pack-year) patient with medical history of chronic obstructive pulmonary disease (COPD) type emphysema (forced expiratory volume in the first second (FEV1)/forced vital capacity (FVC): 46%, FEV1: 70% and carbon monoxide diffusing capacity (DLCO): 49%) under bronchodilator treatment and periodical follow-up by a pulmonologist was admitted in a non-tertiary care hospital due to dyspnea, cough, myalgia and fever. The patient presented an acute respiratory failure with hypoxemia and hypcapnia. The polymerase chain reaction (PCR) microbiological test in nasopharyngeal exudate revealed SARS-CoV-2 nucleic acid and the chest radiography showed right basal opacities and a diffuse interstitial bilateral pattern (Fig. 1A). The patient was diagnosed with COVID-19 pneumonia and he was treated with hydroxychloroquine, lopinavir/ritonavir, interferon beta, corticoids and non-invasive ventilation. After 10 days of hospitalization, the patient was discharged with home oxygen and the recommenda-

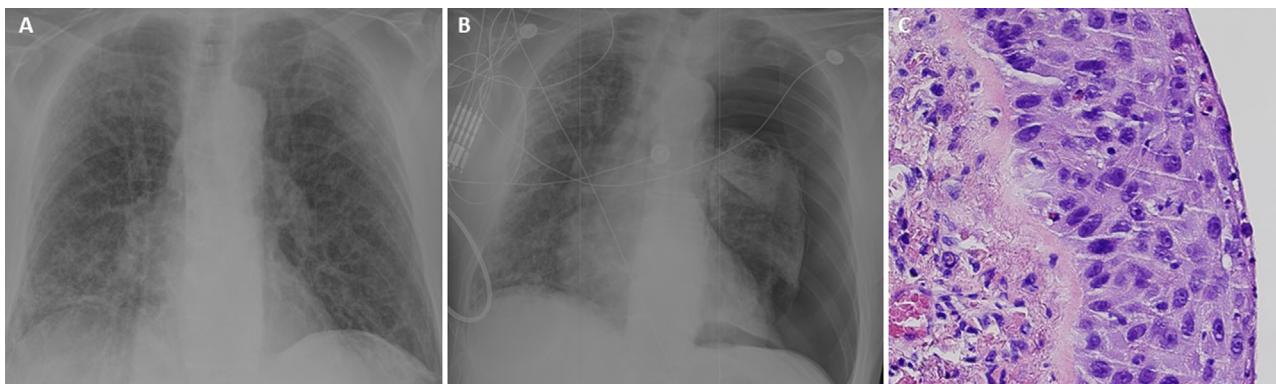

Fig. 1. (A) Chest radiography showing right basal opacities and a diffuse interstitial bilateral pattern compatible with COVID-19. (B) Chest radiography showing a left complete pneumothorax and persistence of the radiological changes due to the COVID-19. (C) Microscopical detailed view of atypical cellularity with a high mitotic index (squamous cell carcinoma).

tion of solitary confinement for 14 days. During the 4th day of individual isolation, he developed acute dyspnea and chest pain and he was transferred to the hospital again. A left complete pneumothorax was seen in the chest radiography (Fig. 1B). A 20F chest tube was inserted and a continuous 3/5 air leak was observed in the analogic drain. The patient was kept in isolation in a COVID-19 restricted area. After 6 days of prolonged air leak and incomplete pulmonary expansion, his general surgeon contacted us to transfer the patient to our third-level university hospital for surgical treatment.

To avoid virus spread, the procedure to transfer a patient from one to another hospital must follow all security protocols. So that, before transferring the patient we performed a new PCR test with a negative result. Once here, since the patient had not complied the 14 days of individual isolation after discharge, a serologic test was ordered to verify if the infection was active or passed; the result was positive, but unfortunately there was no possibility to know about which kind of immunoglobulins was elevated (Ig G or Ig M) due to the lack of reactants. So that, a new PCR test was performed to confirm the previous one with a delay less than 48 h. The result was negative. Regarding the two last negative tests and the time interval since the first positive test (more than three weeks), the patient was considered as a SARS-CoV-2 negative patient and treated with comprehensive protective measures but without strict isolation in the ward.

The patient underwent video-thoracoscopic surgery. A 2 mm perforation was found in the left segment six in an emphysematous area and a wedge resection and chemical pleurodesis were performed. The patient was discharged the day after the operation with no complications. The anatomopathological report revealed a keratinizing squamous cell carcinoma in situ in an emphysematous bulla with free surgical margins (Fig. 1C). Non-tumoral parenchyma characterized by the subpleural cyst wall thickness.

After complete recovery of the patient, a thoraco-abdominal computerized tomography (CT) and a positron emission tomography-CT (PET-CT) were performed. No distant metastases or nodal disease were detected. Final staging was pTisNOMO (stage 0).

As thoracic surgeons the new scenario we face is treating COVID-19 patients or patients who recently overcome the disease who present with non-related COVID-19 pathology which require urgent or preferential thoracic surgical intervention. A recent study has demonstrated that postoperative pulmonary complications occur in half of patients with perioperative SARS-CoV-2 infection and are associated with high mortality.² Moreover, Li et al.³ concluded that COVID-19 is associated with poor prognosis for patients undergoing thoracic operation, especially for those with COPD. So

that, unnecessary thoracic surgeries should be avoided. Besides, since it is imperative to ensure the safety of health-care workers not only to safeguard continuous patient care but also to ensure they do not transmit the virus, high-sensitivity diagnostic tests should be routinely performed to identify current and past infection (serologic tests) and to ensure that patients who have overcome the disease are no longer contagious (nucleic acid tests).

Until a few days ago, only urgent procedures and high priority oncological elective surgery in non-COVID-19 patients were performed and always balancing the risk of delaying therapy against the availability of hospital resources and potential exposure of COVID-19 on a case-by-case basis. In addition, whenever possible, the elective surgical activity has been transferred to COVID-free areas to avoid potential contracting intra-hospital infections. Since previous reports have revealed that there are asymptomatic patients infected with SARS-CoV-2,^{4,5} all patients needing a surgical intervention should be tested.

We report the case of a patient presented with left spontaneous pneumothorax after discharge for COVID-19 pneumonia that was managed surgically. We consider this therapy was non-delayable and, after microbiological verification of SARS-CoV-2 negativity, excision of a perforated bulla was performed. Pathological examination of the specimen revealed a lung carcinoma in situ whose prognosis is excellent.

Ivermectin Treatment May Improve the Prognosis of Patients With COVID-19

El tratamiento con ivermectina puede mejorar el pronóstico de los pacientes con COVID-19

Dear Editor:

The pandemic coronavirus disease 19 (COVID-19), caused by severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), has been spread rapidly worldwide with considerable morbidity and mortality. COVID-19 patients have various clinical presentations: asymptomatic, exhibit mild flu-like symptoms, be severely ill or death.^{1,2} In addition to elder age and comorbidities, higher levels of D-dimer and C-reactive protein (CRP) and lower levels of lymphocyte and eosinophil as well as a cytokine storm are associated with disease severity in COVID-19 patients.^{3–6} The virus load may be a main determinant underlying the pathological diversity in COVID-19 patients.^{1,2,6} Thus, an effective antiviral treatment is essential to improve the prognosis of patients with COVID-19.⁷ In the absence of specific anti-SARS-CoV-2 agents, various drugs with antiviral potential are now used to contain the virus in COVID-19 patients. Ivermectin, a US FDA-approved anthelmintic, has garnered enormous interest for treating COVID-19 as it is safe and cheap and has strong antiviral activities against broad ranges of viruses including SARS-CoV-2 *in vitro*.^{8–10} Despite the widespread use of ivermectin, to our knowledge, there is currently no published clinical reports of ivermectin in COVID-19 patients. Here, we assessed the clinical efficacy of ivermectin in COVID-19 patients.

This retrospective study enrolled a total of 325 consecutive patients with SARS-CoV-2 infection confirmed by polymerase chain reaction (PCR) of nasal swabs in SK hospital, a unit dedicated to COVID-19 at Mymensingh Medical College Hospital (MMCH), Mymensingh, Bangladesh, from April to June 2020. Of these, the present study included 248 adult COVID-19 patients free from any other serious pathological conditions: 115 received ivermectin plus standard care (SC), while 133 received only SC. Remaining 77 patients who were under 18 years of age or transferred from other facilities and received different management approaches including partial hospital stays or treated with different therapeutic agents prior to hospital admission were excluded from the analysis. The two groups were compared in terms of time to SARS-CoV-2 negativity, disease progression (develop pneumonia to severe respiratory distress), duration of hospital stays, and mortality rate. Ivermectin was given once at dose of 12 mg within 24-h after hospital admission. SC was provided as required and included antipyretics for fever, anti-histamines for cough, and antibiotics to control secondary infection. The study was approved by MMCH and informed consent was obtained from all patients or their relatives before starting treatment. Categorical variables are shown as frequencies and percentages and continuous variables as the median and interquartile range (IQR). Differences with 95% confidence intervals (CI) were computed to show the level of certainty. Paired *t*-tests or Pearson Chi-square test were used to analyze statistical differences. All calculations were performed using SAS, version 9.4 (Cary, NC, USA).

The median age of the patients was 35 (IQR 30–43) years and 60% were men. Table 1 summarizes the demographics and clinical presentations of the two groups. At the time of admission, all patients had comparatively mild/moderate disease with cough, headache, sore throat, anosmia, breathing difficulty, and pneumonia in different proportions. Some patients in both groups had underlying comorbidities like hypertension, diabetes mellitus, asthma, and hyperlipidemia. About 13% of the patients were current smokers. Also, about 58% had higher D-dimer and CRP levels, 51% had lymphopenia, and 47% had eosinopenia. However, at the time of admission, there were no significant differences in the patient profiles, presenting symptoms, comorbidities and hemato-biochemical parameters of the two treatment groups (Table 1).

The treatment did not produce any aberrant symptoms related to ivermectin use. None of the ivermectin-treated patients showed progressive pathology, such as pneumonia or cardiovascular complications (Table 1). On the other hand, 9.8% patient developed pneumonia and 1.5% had ischemic stroke those were not received ivermectin. Significantly fewer ivermectin-treated patients required oxygen inhalation (9.6% vs. 45.9), developed respiratory distress (2.6% vs. 15.8%), or needed antibiotic treatment (15.7% vs. 60.2%) and intensive care management (0.9% vs. 8.3%). Interestingly, the patients receiving ivermectin became SARS-CoV-2 negative more quickly (median 4 vs. 15 days; 95% CI, 8.97–10.59; $P < 0.001$). The ivermectin-treated patients also had shorter hospital stays (median 9 vs. 15 days; 95% CI, 5.09–7.51; $P < 0.001$). Furthermore, the mortality rate was significantly lower in the ivermectin group than SC (0.9% vs. 6.8%; $P < 0.05$; Table 1). Of the ivermectin-treated patients, 61 were randomly assigned for follow-up assessment 10 and 20 days after discharge; none of them reported any complications.

After SARS-CoV-2 infection, the disease generally progresses within 1 week of symptom onset due to uncontrolled viral replication in the upper respiratory tract,^{2,6,11,12} followed by immune anomalies, and a cytokine storm.^{2,5,6} Thus, an effective antiviral therapy capable of blocking viral replication at the earliest time after infection may prevent disease progression. This study shows that ivermectin is safe in COVID-19 patients and efficient at rapidly clearing SARS-CoV-2 from nasal swabs (median 4 days). This was much shorter than in the COVID-19 patients receiving only SC (15 days) or receiving a combination of three antiviral drugs (7–12 days¹³). Furthermore, in terms of developing respiratory distress leading to ICU admission and the final outcome (discharge/death), we observed a significant clinical benefit of ivermectin in COVID-19 patients. In fact, with ivermectin, we observed quick hospital discharge (median 9 days) in 114 out of 115 patients; the remaining patient arrived with advanced disease.

Ivermectin induced rapid virological clearance that we observed in this study indicating that the preclinical efficacy of the drug against SARS-CoV-2⁹ may be mirrored in patients. Such rapid clearing of SARS-CoV-2 (median 4 days); this is much shorter than the median duration (20 days) of viral shedding in patients with COVID-19,¹⁴ indicate that ivermectin could limit the viral spreading. Collectively, the present findings suggest that ivermectin induced rapid SARS-CoV-2 clearance could reduce COVID-19 disease progression and community transmission.
