A Corrigendum on

Spotlight on the Energy Harvest of Electroactive Microorganisms: The Impact of the Applied Anode Potential

by Korth, B., and Harnisch, F. (2019). *Front. Microbiol.* 10:1352. doi: 10.3389/fmicb.2019.01352

In the original article, Equation (11) that described the degree of exploitation of the thermodynamic frame by the microorganisms was misleading and has to be corrected for a more precise explanation. The symbol C_{Ac-} (acetate concentration) has to be replaced by r_{Ac-} (rate of acetate degradation). Therefore, the result of Equation (11) is microbial energy harvest ($U_{Harvest}$) and not microbial action (S_M).

A correction has been made to the section **Modeling the Energy Harvest of Electroactive Microorganisms:**

The degree of exploitation of the thermodynamic frame can be illustrated by means of microbial energy harvest ($U_{Harvest}$, Equation 11)⁶. In the model, it represents the energy harvest from acetate oxidation integrated over biofilm thickness and time. Thereby, acetate gradients across biofilm thickness and during time are considered for calculations (Equation 11).

Equation (11) in the section **Modeling the Energy Harvest of Electroactive Microorganisms** was corrected:

$$U_{Harvest} = \int_0^t \left(\int_0^{L_{Biofilm}} \Delta_R G_{Cat} r_{Ac-} dx \right) dt A_A \quad (11)$$

Accordingly, **Figure 2D** and the legend of **Figure 2** in the section **Modeling the Energy Harvest of Electroactive Microorganisms** were corrected and appear below:

⁶ A_A is projected anode area.

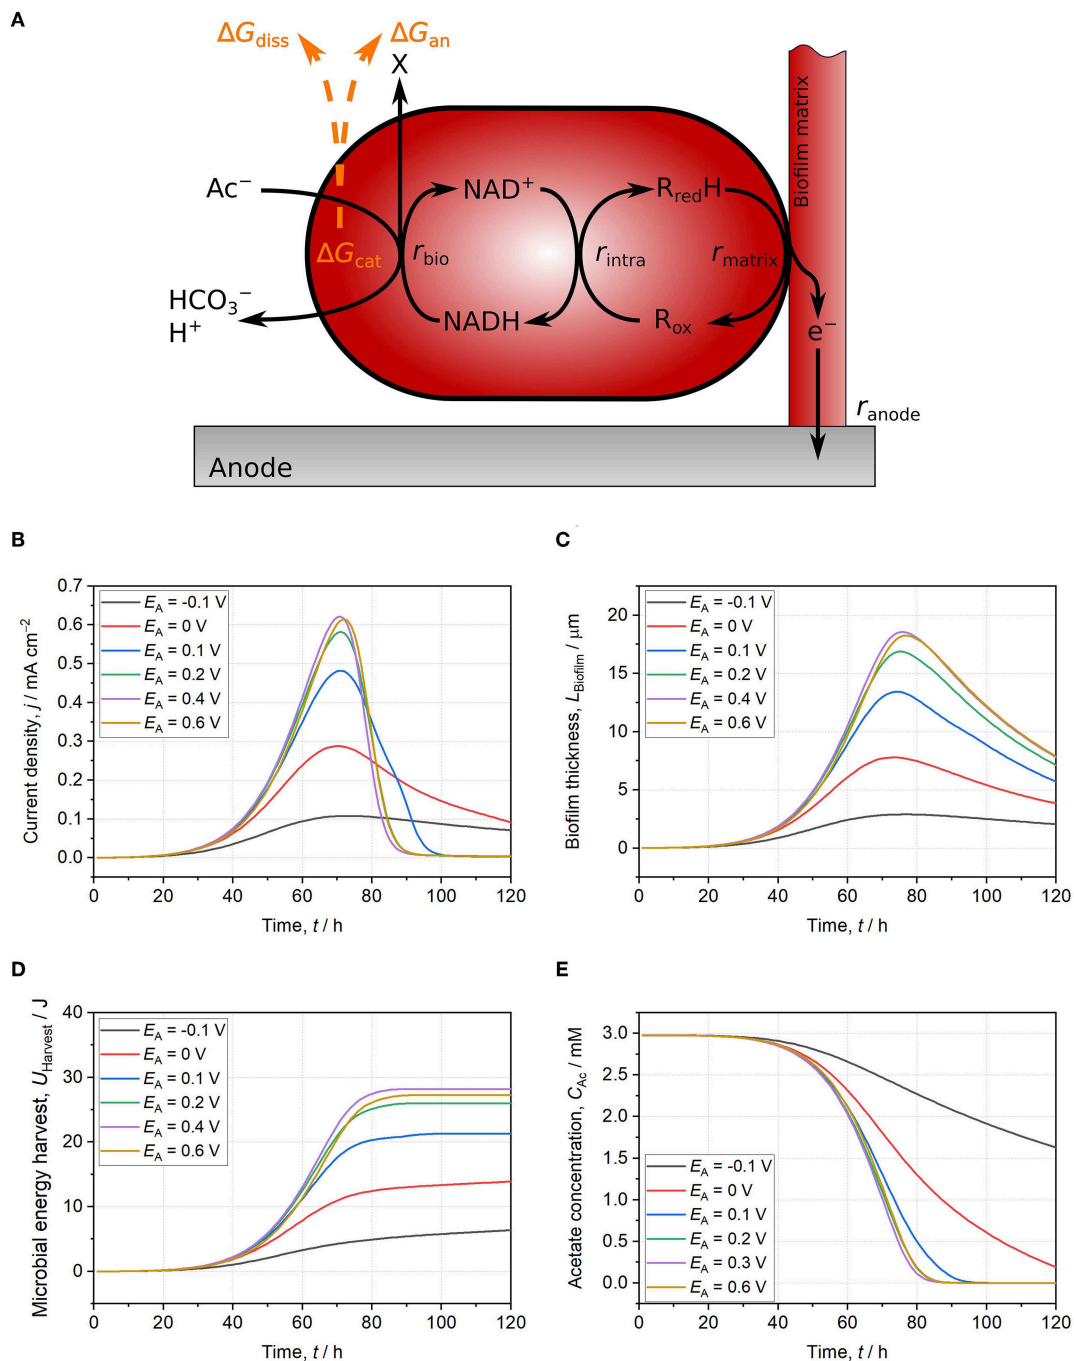

FIGURE 2 | Schematic illustration of the used model and model results for *Geobacter* spp. biofilms growing on anodes set to -0.1 V (black line), 0 V (red line), 0.1 V (blue line), 0.2 V (green line), 0.4 V (purple line), and 0.6 V (yellow line). **(A)** Schematic model representation: Acetate oxidation is coupled to NAD^+ reduction resulting in energy harvest (ΔG_{cat}) subsequently used for the build-up of biomass (ΔG_{an}) and for providing driving force for growth (ΔG_{diss}). Electrons are then transferred to intracellular cytochromes and further to a conductive biofilm matrix. Finally, electrons are donated to the anode. All reactions occur at individually calculated rates (r_{bio} , r_{intra} , r_{matrix} , r_{anode}) (Korth et al., 2015). **(B)** Current density. **(C)** Biofilm thickness. **(D)** Microbial energy harvest. **(E)** Acetate concentration. With anode potentials ≤ 0.1 V, the thermodynamic frame defined by acetate, $NAD^+/NADH$ ratio, and other reactants is not fully exploited. Slow EET kinetics result in thermodynamically unfavorable reaction conditions for catabolic reaction (i.e., low $NAD^+/NADH$ ratio) leading to lower current density, biofilm thickness, and microbial energy harvest at comparable acetate consumption. For anode potentials ≥ 0.2 V, direct EET is not limiting catabolism and reaction conditions are thermodynamically improved. Consequently, current density, biofilm thickness, and microbial energy harvest do not further increase with higher potentials. The model is based on separated anodic compartment (volume = 250 mL, anode area = 10 cm²) and cathodic compartment via a membrane (membrane area = 10 cm²). Acetate concentration is 3 mM, phosphate buffer concentration is 50 mM, and initial pH is 6.95 . Further model parameters are detailed in Supplementary Table S1 and Korth et al. (2015).

Additionally, the section **Discussion** was corrected:

In the model, microbial energy harvest saturates at $E_A \geq 0.2$ V and a further increase of the anode potential does not lead to higher microbial energy harvest.

The authors apologize for this error and state that this does not change the scientific conclusions of the article in any way. The original article has been updated.
