ABSTRACT

Objective To determine the prevalence of potentially inappropriate medications (PIMs) at admission and discharge among hospitalised elderly patients with acute medical illness in Japan.

Design A retrospective single-centre cross-sectional study.

Participants Hospitalised patients aged 65 years or older admitted for pneumonia, heart failure, ischaemic stroke, acute coronary syndrome, chronic obstructive pulmonary disease or asthma, gastrointestinal bleeding, urinary tract infection or epilepsy from September 2014 to June 2016 who were still alive at discharge.

Main outcome measures The primary outcome was the proportion of patients taking at least one PIM at admission and discharge. PIMs were defined based on the 2015 American Geriatric Society Beers Criteria. Temporal changes in the proportion of patients taking at least one PIM from admission to discharge were also evaluated.

Results During the study period, 689 eligible patients were identified. The median patient age was 82.0 years (IQR 76.0–88.0), 348 (50.5%) were men and the median number of medications at admission was 5.0 (IQR 3.0–8.0). The proportions of patients taking any PIMs at admission and discharge were 47.9% (95% CI 44.2% to 51.6%) and 25.1% (95% CI 21.9% to 28.4%), respectively. The proportion of patients taking any PIMs was significantly lower at discharge than at admission (reduction rate 0.48, 95% CI 0.41 to 0.53).

Conclusions A substantial proportion of hospitalised elderly patients with acute medical illness took PIMs at admission and discharge. These findings should be confirmed at other hospitals in Japan.

INTRODUCTION

Polypharmacy is a common problem among elderly patients due to the high prevalence of multiple morbidities,^{1 2} and it is associated with the use of potentially inappropriate medications (PIMs).^{3 4} PIMs have been defined as medications that have an unfavourable

Strengths and limitations of this study

- This is the first study to evaluate the temporal change in the prevalence of potentially inappropriate medication (PIM) use from admission to discharge among hospitalised elderly patients with acute medical illness in Japan.
- This study was conducted at a single hospital in Japan with a small sample of patients.
- The prevalence of PIM use after discharge was not evaluated.

balance between the benefit and harm they cause for many elderly adults.⁵ Several geriatric experts have proposed medication lists regarding PIMs that should be avoided as much as possible for elderly adults.^{6–8} Although PIMs are associated with a risk of harmful events,^{9 10} they are commonly taken by elderly patients,^{4 11} particularly in acute care settings such as hospitals.^{12 13} Therefore, it is important to monitor the prevalence of PIM use among hospitalised elderly patients with acute illness.

The prevalence of PIM use at admission in hospitalised elderly patients with acute illness in past studies was found to range from 20% to 70%.^{12 14–24} Furthermore, the prevalence of PIM use is often unchanged or increased at discharge,^{14–18} although some studies have reported that geriatric care unit admission reduced the use of PIMs from admission to discharge among elderly patients with acute medical illness.^{19–24} However, to the knowledge of the author, no studies have been conducted to investigate the prevalence of PIM use at admission and discharge among hospitalised elderly patients in Japan. Thus, the aim of this study was to determine the

prevalence of PIM use at admission and discharge among this patient population.

METHODS

Study design and participants

This was a retrospective cross-sectional study using the database of the National Hospital Organisation Tochigi Medical Centre, and data from September 2014 to June 2016 were collected. The National Hospital Organisation Tochigi Medical Centre is a 350-bed community hospital in the Tochigi Prefecture of Japan. It is one of the two largest acute care hospitals in this area, serving approximately 0.5 million individuals. In this hospital, there are no geriatricians or geriatric care units. The aim of this study was to determine the prevalence of PIM use at admission and discharge among hospitalised elderly patients with acute medical illness. All consecutive patients aged 65 years or older who were admitted to the hospital for eight common disease categories (heart failure, pneumonia, ischaemic stroke, gastrointestinal bleeding, urinary tract infection (UTI), chronic obstructive pulmonary disease (COPD) or asthma, acute coronary syndrome and epilepsy) were included. As comorbidities can affect PIM use,⁴ the primary diagnosis for admission might also affect PIM use for hospitalised elderly patients. Therefore, patients were included according to their primary diagnosis for admission. Patients who died during their hospital stay or were transferred to the surgical ward or other hospitals within a few days after admission were excluded. Patients with a second admission due to the same disease during the study period were also excluded. Individual informed consent was not required because only data from medical records were used, and the patients were not contacted. The study protocol was approved and was carried out in accordance with the Declaration of Helsinki.

Data collection and patient characteristics

Data were collected using the electronic medical records of the National Hospital Organisation Tochigi Medical Centre. Information on age, gender, primary diagnosis for admission, social history, medical history, Charlson Comorbidity Index (CCI)²⁵ and medication use was retrieved from electronic medical records at the time of the patient's first admission. In this hospital, a comprehensive list of current medications is routinely compiled by pharmacists after admission. Medication management during hospitalisation was performed by the principal physician, who also determined and documented prescriptions at discharge. Therefore, information on medications at admission was retrieved from the comprehensive list compiled by pharmacists. Information on medications at discharge was based on the discharge prescriptions issued by principal physicians. The discharge prescriptions included all regular medications that were used at discharge. These included oral medications, inhalers and injections. As-needed medications for chronic disease were also included. However, eye drops, intranasal infusers, over-the-counter drugs and topical

medications were excluded. Medications that were indicated for apparent transient disease were also excluded because one of the aims of this study was to evaluate the temporal change in the PIM prevalence from admission to discharge in terms of regularly prescribed medications. Furthermore, given that misdiagnosis is common in elderly patients^{26 27} and that upper respiratory tract infection is often the trigger of heart failure, the inclusion of medications that were indicated for apparent transient disease overestimates the temporal reduction of PIM prevalence from admission to discharge. For example, antitussive medications for the common cold and antibiotic agents for a UTI and pneumonia were not included. Newly started medications were defined as medications that were not prescribed at admission but were prescribed at discharge.

Outcome measures

The primary outcome was the proportion of elderly patients with acute medical illness taking at least one PIM at admission and discharge. This outcome was also evaluated for subgroups of patients with the eight common medical illnesses mentioned above, classified according to their primary diagnosis at admission. PIMs were defined based on the 2015 Beers criteria of the American Geriatric Society.⁶ Two of the five components of the Beers criteria were used: PIM use in elderly adults and PIM use in elderly adults that is determined by drug–disease or drug–syndrome interactions that may exacerbate the disease or syndrome. These two parts were chosen because they have existed since the 1997 Beers criteria.^{28–30} In Japan, few methods for evaluating the appropriateness of medication use among elderly patients have been tested or validated. However, some studies have found that the Beers' criteria might be applicable in a Japanese setting,^{31 32} and the Beers' criteria are the most frequently used criteria for this topic in Japanese research. Therefore, the Beers criteria were chosen. The number of PIMs according to drug subcategories was also evaluated.

Given that the 2015 Beers criteria targeted only the long-term use of proton pump inhibitors (PPIs),⁶ most PPIs that were newly started during hospitalisation, regardless of the appropriateness of their use, were not judged to be PIMs at discharge because the duration of hospital stay was often ≤ 8 weeks.³³ Moreover, the Beers criteria definition of high-risk patients for whom prophylactic use of PPIs is appropriate was ambiguous. Therefore, based on a previous study³⁴ and the American College of Gastroenterology guidelines,^{35–37} PPI therapy was judged to be potentially inappropriate if the patients had none of the following indications: (1) peptic ulcer disease; (2) gastro-oesophageal reflux disease with or without oesophagitis; (3) *Helicobacter pylori* eradication therapy; (4) pathological hypersecretory conditions, such as Zollinger-Ellison syndrome; (5) use of non-steroidal anti-inflammatory drugs (NSAIDs); (6) use of antiplatelet therapy and at least one risk factor (history of peptic ulcer or concomitant use of anticoagulants or corticosteroids).

Figure 1 Flow chart of the 689 hospitalised elderly patients with the eight targeted acute medical illnesses.

Statistical analysis

A sample size calculation was not performed prior to data collection. Hospitalised patients were screened starting in September 2014 because this was when the hospital started using electronic medical records. Descriptive statistics were used to describe the study population. For the primary outcome, the proportion of patients taking any PIMs at admission and discharge among all patients was calculated. This proportion was also determined for subgroups of patients classified according to their primary diagnosis for admission. The 95% CIs were calculated for these outcomes. The number of all medications at admission was compared with the number of all medications at discharge using a two-tailed paired t-test. A comparison of the proportion of patients taking any PIMs at admission and at discharge was performed by using Fisher's exact test. The rates of reduction in the proportion of patients taking any PIMs from admission to discharge were also calculated. To identify the predictive factors of

the use of any PIMs at discharge, a multivariate analysis using binary logistic regression was conducted to examine the associations between the use of any PIMs at discharge and selected variables. Based on previous studies,^{16 20 22 24} the following variables were entered in the logistic regression model: age, gender, CCI, number of total medications at admission and duration of hospital stay. These analyses were carried out using the Excel statistical software package V.2.11 (Bellcurve for Excel; Social Survey Research Information Co., Tokyo, Japan) or Stata V.15 (LightStone, Tokyo, Japan), and the level of significance was set at 5%.

Patient and public involvement statement

No patients were involved in determining the research question or outcome measures nor were they involved in developing plans to design or implement the study. No patients were asked for advice during the interpretation or writing up of the results. There are no plans to

disseminate the results of this research to study participants or the relevant patient community.

RESULTS

During the study period, 2297 patients aged 65 years or older were admitted. Out of 1848 admissions, after 449 elective admissions were excluded, 887 admissions were due to one of the eight targeted acute illnesses, 105 were excluded because of in-hospital death and 19 were excluded because of immediate transfer after admission to a surgical ward or another hospital. Additionally, 74 were excluded because of a second admission due to the same primary diagnosis during the study period. A total of 689 patients were thus included in the final analysis (figure 1). The primary diagnoses of these patients were heart failure (n=153, 22.2%), pneumonia

(n=141, 20.5%), ischaemic stroke (n=108, 15.7%), gastrointestinal bleeding (n=71, 10.3%), UTI (n=58, 8.4%), COPD or asthma (n=57, 8.3%), acute coronary syndrome (n=56, 8.1%) and epilepsy (n=45, 6.5%).

The baseline characteristics of the patients are presented in online supplementary table S1. Of the 689 patients, the median age was 82.0 years (IQR 76.0–88.0), 348 (50.5%) were men, the median CCI was 2.0 (IQR 1.0–3.0), 168 (24.4%) had dementia and 94 (13.6%) were institutional residents. The median duration of hospital stay was 16.0 days (IQR 10.0–29.0).

Table 1 shows the number of medications at admission, the number newly started during hospitalisation and the number at discharge among the hospitalised elderly patients according to their primary diagnosis for admission. The median number of medications taken

Table 2 The temporal change in the proportion of hospitalised elderly patients taking any PIMs from admission to discharge according to their primary diagnosis for admission. Values are given as numbers (percentages) unless stated otherwise

Primary diagnosis for admission	Proportion of patients taking any PIMs*			
	At admission	At discharge	Reduction rate (95% CI)	P values†
Total, n=689	330 (47.9)	173 (25.1)	0.48 (0.41 to 0.53)	<0.001

*PIMs were defined based on the 2015 American Geriatric Society Beers Criteria.

†Comparison of the numbers at admission and at discharge using Fisher's exact test.

ACS, acute coronary syndrome; COPD, chronic obstructive pulmonary disease; GI, gastrointestinal; PIM, potentially inappropriate medication; UTI, urinary tract infection.

Table 3 Summary of the multivariate logistic regression results* for predicting the use of any PIMs† at discharge

Variables	OR (95% CI)	P values
Age	0.97 (0.96 to 0.97)	0.02
Women	1.70 (1.17 to 2.48)	0.01
Charlson Comorbidity Index	1.03 (0.92 to 1.16)	0.56
Number of medications at admission	1.20 (1.14 to 1.27)	<0.001
Duration of hospital stay	1.00 (1.01 to 1.00)	0.96

*The following variables were used: age, gender, Charlson Comorbidity Index, number of medications at admission and duration of hospital stay.

†PIMs were defined based on the 2015 American Geriatric Society Beers Criteria.

PIM, potentially inappropriate medication.

by all patients was significantly lower at discharge than at admission (4.0 (IQR 2.0–5.0) and 5.0 (IQR 3.0–8.0), respectively; $p < 0.001$), although a median of 1.0 new medications (IQR 0.0–2.0) were started during hospital stays. All the subgroups of patients classified by primary diagnosis for admission, except those admitted for an acute coronary syndrome, showed similar temporal changes in the median number of medications from

admission to discharge. **Table 2** shows the proportion of patients taking any PIMs at admission and at discharge according to their primary diagnosis for admission. The proportion of patients taking any PIMs at admission was 47.9% (95% CI 44.2% to 51.6%), while the proportion of patients taking any PIMs at discharge was 25.1% (95% CI 21.9% to 28.4%). The proportion of patients taking any PIMs was significantly lower at discharge than at admission (reduction rate 0.48, 95% CI 0.41 to 0.53). The subgroups classified by primary diagnosis for admission showed similar changes in the proportion of PIM use from admission to discharge. In the multivariate analysis using binary logistic regression, younger age, female gender and increasing number of medications at admission were independently associated with a higher risk of the use of any PIMs at discharge (**table 3**). However, CCI and duration of hospital stay were not statistically significant predictive factors for the use of any PIMs at discharge.

Table 4 shows the number of PIMs according to drug subcategories at admission and discharge. Of all medications that were PIMs at admission, 341 (66.9%) were discontinued during hospitalisation or were not PIMs at discharge (online supplementary table S2). The most common PIMs used at admission and discharge were benzodiazepines, PPIs and non-benzodiazepine

Table 4 Total number of PIMs* according to the subcategories of drugs taken at admission, newly started during hospitalisation and taken at discharge

Drug category	At admission	Newly started†	At discharge	P values‡
Total	510 (100.0)	50 (100.0)	219 (100.0)	<0.001
Benzodiazepines	141 (27.6)	7 (14.0)	65 (29.7)	<0.001
Proton pump inhibitors§	129 (25.3)	23 (46.0)	83 (37.9)	<0.001
Hypnotics (non-benzodiazepines)	38 (7.5)	5 (10.0)	21 (9.6)	0.001
Antipsychotics	36 (7.1)	1 (2.0)	15 (6.8)	<0.001
NSAIDs	28 (5.5)	0 (0.0)	0 (0.0)	<0.001

§PPI therapy was judged to be potentially inappropriate if the patients had none of the following indications: (1) peptic ulcer disease; (2) GERD with or without oesophagitis; (3) *Helicobacter pylori* eradication therapy; (4) pathological hypersecretory conditions, such as Zollinger-Ellison syndrome; (5) use of NSAIDs; (6) use of antiplatelet therapy and at least one risk factor (history of peptic ulcer or concomitant use of anticoagulants or corticosteroids).

GERD, gastro-oesophageal reflux disease; NSAIDs, non-steroidal anti-inflammatory drugs; PIM, potentially inappropriate medication; PPI, proton pump inhibitor.

hypnotics. These three categories comprised more than 60% of the total PIMs at admission and discharge.

DISCUSSION

The results of this study show that the proportion of patients taking at least one PIM at admission among hospitalised elderly patients with acute medical illness was 47.9%. Regardless of the primary diagnosis for admission, more than two-fifths of the patients took at least one PIM at admission. Furthermore, approximately one-fourth of all patients took at least one PIM at discharge, although the proportion of patients taking at least one PIM decreased significantly from admission to discharge.

To the knowledge of the author, this is the first study to determine the prevalence of PIM use at admission and discharge among hospitalised elderly patients with acute medical illness in Japan. Although one Japanese multicentre prospective study reported the frequency of PIM prescription during hospitalisation, this study did not aim to investigate the temporal change in PIM prevalence from admission to discharge.³⁸ Therefore, it is unclear whether the proportion of PIM use at admission and discharge among the population in the present study is higher or lower than in other hospitals in Japan due to the lack of comparable studies. However, the prevalence of PIM use among elderly patients at admission and discharge in this study is consistent with that of studies conducted in other countries,^{12 15–24} although the prevalence of PIM use at admission and discharge among elderly patients with acute coronary syndrome in this study was much higher than that of hospitalised elderly patients with acute myocardial infarction in the USA.¹⁴ Given the harmful effects of PIMs for elderly patients,^{9 10} further studies are warranted to confirm these findings in other hospitals in Japan.

Although approximately one-fourth of all patients were taking at least one PIM at discharge, this study shows that there was a significant reduction in the proportion of PIM use from admission to discharge among hospitalised elderly patients with acute medical illness, which is an encouraging finding. This finding is also consistent with that of past studies showing a significant reduction in the proportion of PIM use from admission to discharge among similar patient populations,^{19–24} although some studies reported that the proportion of PIM use did not change or increase from admission to discharge.^{14–18} However, this finding of the present study should be interpreted with caution because most internal medicine physicians who care for hospitalised patients at this hospital make efforts to avoid PIM and polypharmacy for elderly patients in routine practice.³⁹ For example, NSAIDs and antipsychotics are rarely introduced for hospitalised elderly patients in the medical ward of this hospital, as [table 4](#) shows. Therefore, it is unclear whether similar reductions in the proportion of PIM use from admission

to discharge among hospitalised elderly patients with acute medical illness occur in other hospitals in Japan. Considering the unexplained regional variations in the use of PIMs among elderly patients during hospitalisation,^{14 40} these findings need to be confirmed in other Japanese hospitals.

In this study, CCI and duration of hospital stay were not statistically significant predictive factors for the use of any PIMs at discharge. These findings are consistent with those of past studies.^{20 22} Younger age, female gender and increasing number of medications at admission were independently associated with a higher risk of the use of any PIMs at discharge in this study. However, past studies have found mixed results regarding the associations among age, gender and number of medications at admission and the use of any PIMs at discharge.^{16 20 22 24} Therefore, further studies are needed to evaluate the effect of these factors on the use of any PIM use at discharge among hospitalised elderly patients with acute medical illness.

Limitations

These results presented here should be interpreted in the context of several limitations. First, this study used a retrospective design, which might have generated biased data. Second, hospitalised patients who died or were transferred to other settings were excluded, as were patients with acute medical illnesses other than the eight illnesses considered in this study. Given that patients who die during hospitalisation are often older and have a higher burden of comorbidities, the exclusion of these patients might underestimate the prevalence of PIM use at admission. Third, the prevalence of PIM use after discharge was not evaluated. Given that a significant increase in the long-term prevalence of PIM use has been observed among elderly patients who have undergone interventions regarding polypharmacy to reduce PIM use,⁴¹ it remains uncertain whether the reduction in PIM use observed in our study is sustainable over the long term. Therefore, the extent of the reduction of PIM prevalence from admission to discharge observed in the present study might be overestimated. Fourth, this study was limited to a single centre and to elderly patients admitted for eight categories of acute medical illnesses, and therefore, the results cannot be easily generalised. These findings should be confirmed for other acute illnesses and in other hospitals in Japan. Fifth, the length of hospitalisation is relatively longer in Japan than in other countries,⁴² which limits the generalisability of these findings to other countries. However, the multivariate analysis conducted in the present study found no association between PIM use at discharge and the duration of hospital stay. Sixth, drugs classified as PIMs are not necessarily inappropriate.⁵ Furthermore, it is unknown whether reducing PIM use improves clinically important patient outcomes.^{43–45} Seventh, this study used the alternative definition for the potentially inappropriate use of PPIs. Given that this definition

targets both short-term and long-term use, unlike the Beers criteria, the prevalence of the potentially inappropriate use of PPIs might have been overestimated. However, prescriptions for PPIs in elderly patients are often long term (>8 weeks),^{46 47} and PPIs that are newly started during hospitalisation are often continued after discharge.⁴⁸ Finally, our assessment did not include potential prescription omissions⁷ or other clinically important outcomes, such as mortality and adverse drug events.

Implications for clinical practice

The prevalence of PIM use at admission in hospitalised elderly patients with acute medical illness was high in Japan, as it is in other countries. Furthermore, the prevalence of PIM use was still high at discharge, even though hospitalisation due to medical illness can provide a good opportunity to review medications and discontinue inappropriate ones.⁴⁹ Given the harmful effects of PIMs for elderly patients,^{9 10} further studies are needed to develop an approach for minimising PIM use in the inpatient setting.¹⁴

CONCLUSIONS

A substantial proportion of hospitalised elderly patients with acute medical illness in the present study took PIMs at admission and discharge. Given the harmful effects of PIMs on elderly patients, these findings should be confirmed at other hospitals in Japan.
