

Since January 2020 Elsevier has created a COVID-19 resource centre with free information in English and Mandarin on the novel coronavirus COVID-19. The COVID-19 resource centre is hosted on Elsevier Connect, the company's public news and information website.

Elsevier hereby grants permission to make all its COVID-19-related research that is available on the COVID-19 resource centre - including this research content - immediately available in PubMed Central and other publicly funded repositories, such as the WHO COVID database with rights for unrestricted research re-use and analyses in any form or by any means with acknowledgement of the original source. These permissions are granted for free by Elsevier for as long as the COVID-19 resource centre remains active.

Hyperlipasemia and Potential Pancreatic Injury Patterns in COVID-19: A Marker of Severity or Innocent Bystander?

Keywords: COVID-19; SARS-CoV-2; Lipase; Hyperlipasemia; Pancreatitis; Severity; Clinical Outcome.

Coronavirus disease 2019 (COVID-19) is caused by severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2). Gastrointestinal symptoms in COVID-19 are being reported increasingly.¹ Data on the involvement of the pancreas in COVID-19 have been emerging, and multiple case reports of SARS-CoV-2–induced acute pancreatitis have been published in the literature.² Angiotensin-converting enzyme-2 is the target receptor of SARS-CoV-2 and is expressed abundantly by both the exocrine and endocrine pancreatic tissues.³ The presence of angiotensin-converting enzyme-2 in the pancreas could make it susceptible to SARS-CoV-2, resulting in interstitial leakage of pancreatic lipase, adipose tissue lipolysis, and potentially toxic fatty acid–induced damage. These changes can at least contribute to cytokine storm, multi-organ dysfunction, and COVID-19 morbidity.⁴ Due to its nonspecificity, lipase could be elevated in a myriad of conditions, such as infections, renal dysfunction, medication-related, gastrointestinal, and hepatobiliary disease.⁵ Given this, it is critical to evaluate the prevalence of hyperlipasemia in COVID-19 and predict clinical outcomes.

Methods

We conducted a systematic search using PubMed, Embase, Ovid, and Google Scholar databases from December 1, 2019 to October 9, 2020, to evaluate hyperlipasemia in patients with COVID-19. The following search terms were used: *COVID-19*, *SARS-CoV-2*, *lipase*, *pancreatic injury*, and *pancreas*. The articles with relevant data on the prevalence of hyperlipasemia and its effect on COVID-19 severity were examined. All adult patients with nasopharyngeal reverse transcription polymerase chain reaction positive for SARS-CoV-2 were included in the analysis. Severe COVID-19 was defined as clinical deterioration resulting in adverse clinical outcomes, such as admission to the intensive care unit (ICU), need for mechanical ventilation, or death. Hyperlipasemia was defined as any elevation in lipase levels above the upper limit of the normal reference level. The definition of hyperlipasemia varied among the studies because of differences in the range of lipase levels, as did the definition of severe COVID-19.

OpenMeta[Analyst] software was used to estimate the pooled prevalence of lipase elevations among patients with COVID-19 and the pooled odds ratio for severe COVID-19 among this subset of patients. Results were reported with a 95% confidence interval, and a *P* value of <.05 was considered statistically significant. Heterogeneity was assessed using the *I*² test, and *I*² >50% was taken as a measure of moderate inter-study variation.

Results

The initial search yielded 52 articles. After excluding duplicates and review articles, 7 studies^{3,6–10} (6 retrospective observational studies and 1 prospective observational study¹¹) were included in the pooled analysis. A flow chart depicting the study screening and selection process is presented in [Supplementary Figure 1](#).

Data on the point prevalence of hyperlipasemia were available in all 7 studies, whereas only 4 reported clinical outcomes, ICU admission status, and need for mechanical ventilation or death. The normal range of serum lipase levels differed among the studies. Although 4 studies had an average upper limit of 50–60 U/L, 2 had a higher cutoff (>300 U/L) for lipase levels. Data for 756 patients with COVID-19 were reported in these studies, of which 92 had hyperlipasemia. All of the studies were single-center experiences except two. Two studies defined severe COVID-19 as patients needing ICU admission, 1 study as a need for mechanical ventilation, and only 1 study used a combination of all of the above three to define severe COVID-19. [Supplementary Table 1](#) outlines the baseline characteristics of the included studies.

The results of this pooled analysis are shown in [Figure 1A](#) and [B](#). Among 756 patients with COVID-19 with available lipase levels, the pooled prevalence of hyperlipasemia was 11.7% (95% confidence interval, 0.094–0.140; *P* = .001; *I*² = 0%). The pooled odds ratio for severe COVID-19 in these patients was 3.143 (95% confidence

interval, 1.543–6.400; $P = .003$); mild inter-study heterogeneity was observed ($I^2 = 27\%$).

Discussion

Based on the results of our pooled analysis, hyperlipasemia was found in 11.7% of patients affected by SARS-CoV-2. Patients with COVID-19 with hyperlipasemia are at an approximately 3-fold higher risk of poor clinical outcomes, including need for ICU admission, mechanical ventilation, or death.

Although multiple mechanisms have been proposed for pancreatic injury in COVID-19, the exact etiology remains unclear. Some of the mechanisms include direct pancreatic tissue damage by SARS-CoV-2 and intense inflammatory response (interleukin 1β , interleukin 6, and tumor necrosis factors) with cytokine storm-mediated tissue injury. Furthermore, studies found that patients with COVID-19 with pancreatic injury had a higher prevalence of severe illness on admission; lower levels of CD3⁺ and CD4⁺ T cells; and higher levels of aspartate aminotransferase, γ -glutamyl transferase, creatinine, lactate dehydrogenase, and erythrocyte sedimentation rate.⁶

Limitations of this study include a modest sample size of 756 patients with COVID-19, of which 92 patients had

elevated serum lipase levels. The degree of hyperlipasemia was not uniform across all studies. Potential confounders, such as age, comorbidities, and medication use, could alter the results of this study. Furthermore, a lack of high-quality randomized controlled trials with adjustment for potential confounders is a notable limitation. Given the inclusion of observational studies, selection bias, information bias, and confounding bias are possible. The prevalence of hyperlipasemia could be underestimated due to a lack of testing and nonreporting of the data for many patients.

Severe pancreatic injury resulting in acute pancreatitis might not be a common event in COVID-19. As evidenced by lipase elevation, mild to moderate pancreatic injury is a clinically significant finding in these patients. Future prospective studies are warranted to ascertain the exact impact of lipase elevation in COVID-19 and guide management strategies for these patients.
